Defending Qualitative Change: The View From Dynamical Systems Theory

John P. Spencer
University of Iowa and Iowa Center for Developmental and Learning Sciences

Sammy Perone
University of Iowa

A central controversy in developmental science, enflamed by nativist accounts, is whether development is best viewed as a series of qualitative or continuous changes. This article defends the notion of qualitative change from the perspective of dynamical systems theory (DST). Qualitative change within DST refers to the shift that occurs when a system goes from one attractor state through an instability into a different attractor state. Such changes occur on the second-to-second timescale of behavior. Thus, developmental analysis must always stay local, grounded in the real-time attractor states around which behavior is organized. This article also demonstrates that qualitative and continuous change should not be cast in opposition. They are aligned concepts that work together across multiple timescales.

In his article entitled "In Defense of Qualitative Changes in Development," Kagan (2008) argues that the balance between claims of transformational change and continuity in development has been a central point of controversy throughout the long history of our science. This controversy has reached a head in the past two decades given the growing number of claims of continuity between infants' abilities and the abilities of older children. Many of these claims, Kagan argues, stem from a nativist tradition that has built its reputation, in part, by demonstrating amazing infant abilities and their seeming connection to later forms of cognition (e.g., Meltzoff & Moore, 1977; Wynn, 1992). Kagan argues that such claims of continuity are exaggerated. For instance, the ability of children to use complex semantic networks is qualitatively different from the perceptual schemata formed by infants in looking tasks. Kagan also argues that the empirical evidence of early competence is on tenuous ground given that the empirical record is largely built from a single measure of infant performance—total looking time—which is known to be subject to a host of influences that are often overlooked by researchers interested in showing early competence.

We applaud Kagan's effort to defend the notion of qualitative change. Our article seeks to do the same; however, we take a different tack motivated by our commitment to a particular theory of development—dynamical systems theory (DST). DST was introduced to developmental science in the early 1990s with the publication of *A Dynamic Systems Approach to the Development of Cognition and Action* by Thelen and Smith (1994; for related ideas, see van der Maas & Molenaar, 1992; Van Geert, 1998). These authors, inspired by earlier work on DST in physics, motor control, and psychology, proposed a radical view of development as fluid, multidetermined, and grounded in perception and action (for reviews, see Spencer et al., 2006; Thelen & Smith, 2006). In the past two decades, the concepts of DST have been applied to a host of phenomena including topics in motor development (e.g., Corbetta & Thelen, 1996), cognitive development (e.g., Spencer, Simmering, Schutte, & Schöner, 2007), and socioemotional development (e.g., Lewis, Lamey, & Douglas, 1999).

In the present article, we use this theoretical framework to weigh in on the issue of whether development is best viewed through a qualitative or continuous lens. Our article has two central goals. First, we will define what "qualitative" means from a dynamical systems perspective. Critically, DST provides a precise definition of this concept. This is important because the notion of qualitative development means different things to different researchers, creating conceptual confusion in the literature. Second, we will argue that qualitative changes in behavioral organization actually occur at the timescale of behavior—the second-to-second timescale of thoughts, actions, and emotions. From this view, what changes over learning and development is the emergence of these qualitatively different real-time behavioral states, their stability, and the ability of the infant or child to flexibly shift from one state to another.

We would like to thank Gregor Schöner and Larissa Samuelson for helpful discussions and comments on an earlier version of this article. This work was supported by National Science Foundation HSD 0527698 awarded to J.P.S.

What Does Qualitative Mean?

For many developmental scientists, the term *qualitative* invokes the notion of transformational change—creating something new that was not obviously connected to the something old. A typical example is the transformation that occurs when a caterpillar emerges from a cocoon as a butterfly. What went into the cocoon bears only faint resemblance to what came out. This seems to capture the use of qualitative in the article by Kagan. He highlights that the perceptual schemata hypothesized to underlie infants' behavior bear no obvious resemblance to the semantic networks invoked in childhood.

Although the use of the term *qualitative* in this context has appeal due to its face validity, there is an important tension point—we know that there must be some fundamental, biological connection between the caterpillar and the butterfly. Thus, must there not be continuity as well as discontinuity or transformation? Must the perceptual schemata not be somehow connected to the emergence of the first semantic network?

To further compound the problem, there is now a rich body of evidence showing that apparently abrupt and transformational changes previously thought to reflect qualitative reorganizations in development appear more continuous when examined at finer levels of detail (Adolph, Robinson, Young, & Gill-Alvarez, 2008; Siegler, 1994, 1996). This work has highlighted that the measurement scale and level of analysis can critically effect the conclusions we draw from data about the nature of developmental change, as well as our ability to test theories that make claims about transformational and continuous developmental processes.

Given the diversity of thought regarding the meaning of the term *qualitative,* how this concept relates to developmental continuity and how to measure different types of change, we think the time is ripe to anchor the notion of qualitative development to a detailed theoretical framework. DST has much to offer in this regard: DST offers a precise definition of qualitative change, clear empirical signatures to identify qualitative change, and clarity regarding the link between qualitative and continuous change. Although DST has much to offer, it is difficult to explain dynamical systems concepts succinctly and in a way that resonates with the interests of behavioral researchers. In an effort to achieve both goals, we describe a set of central concepts below using examples that link neural and behavioral dynamics in real time. We then extend these concepts to tackle the issue of qualitative *developmental* change.

Dynamical systems are a class of systems that can be mathematically modeled using equations that specify the rate of change of some variable or system of variables at each moment in time. The idea behind this class of equations is actually quite powerful: If you know the current state of the system and its rate (and direction) of change, that is, how fast the system is moving along some trajectory, then you can take the current state, add the amount you expect it to change, and predict where the system will be at the next point in time.

If we could do this perfectly, we could describe—in detail—the development of a child and predict the state of the child each step along the way. The problem is that the dynamical systems we study in development are extraordinarily complex. Because we cannot know all the details of a complex system, we have to settle for something simpler—we have to study how the system behaves around special points called attractors, points toward which the system gravitates over time. This can get tricky, though, because these special points can actually change themselves. This is what occurs when a qualitative transition happens in a dynamical system: The system shifts from being in the local territory of one attractor to losing that attractor and gravitating toward a new one. The question is: How do we know when one attractor becomes unstable and another attractor emerges (which is formally called a bifurcation; see Braun, 1994)?

Figure 1 provides an overview that answers this question. This figure also illustrates how difficult it can be to identify qualitative shifts in the dynamics of a system. Figures 1A to 1C show a set of stimulus events—inputs to a hypothetical brain of a hypothetical child—turning on and off from second to second as might occur in an infant habituation experiment (see, e.g., Schöner & Thelen, 2006). These figures also show the activation of one simple neuron in the child's brain. Note that in all the simulation examples in this article, we will talk about an example neuron to pick the simplest case possible that is still directly relevant to behavior. Importantly, however, all the concepts we introduce are applicable to the more complex neural fields described in many of our articles (e.g., Simmering, Schutte, & Spencer, 2008; Spencer & Schöner, 2003; Spencer et al., 2007). Moreover, these dynamics can be found in real cortical fields (Amari, 1977; Amari & Arbib, 1977) and measured in real brains using electrophysiology (Bastian, Riehle, Erlhagen, & Schöner, 1998; Bastian, Schöner, & Riehle, 2003; Erlhagen, Bastian, Jancke, Riehle, & Schöner, 1999; Jancke et al., 1999).

As can be seen in Figure 1A, the first exemplary neuron shows a rather complex pattern of behavior:

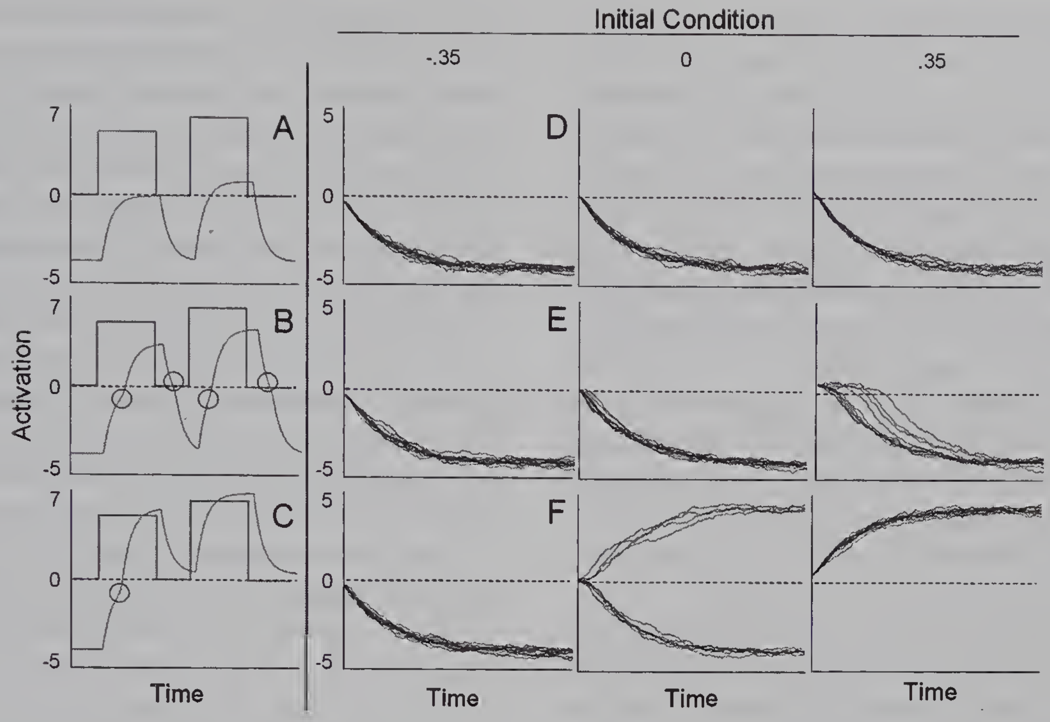

Figure 1. Simulations of a simple neural system to illustrate the concept of qualitative change within dynamical systems theory: (A) the behavior of a neuron with linear dynamics in response to input, (B) the behavior of a self-stabilized neuron, and (C) the behavior of a self-sustaining neuron.

Note. Rectangular inputs are shown in gray. Circles denote qualitative transitions in neural activation. Panels in (D), (E), and (F) show repeated simulations of the neurons simulated in (A), (B), and (C) with different initial activation values (−0.35, 0, or 0.35) and a small amount of noise.

Its activation rises and falls with an exponential pattern as each stimulus is presented, and the overall level of activation covaries with the stimulus strength. Given the nonlinear behavior of this neuron, one might guess that a nonlinear dynamical system is at work that goes up toward one attractor state when the input is on and down toward a qualitatively different state when the input is off. And because the details of the attractor state shift as the input shifts, one might invoke the idea that that system rises to a more advanced or richer encoding of the stimulus when the second input is presented.

It turns out that this analysis is only partially correct. The neuron in Figure 1A is moving toward a higher level of activation when the input is on and a lower level of activation when the input is off. Critically, however, there is no qualitative shift in the dynamics of this system whatsoever. Rather, the activation profile shown in Figure 1A was produced by a simple *linear* dynamical system with a *single* attractor state that the neural activation is moving toward across the duration of this simulation. Why does the neural activation go up and down? This occurs because the location of the attractor in activation space moves as the input is turned on and off.

In contrast to Figure 1A, the simulation shown in Figure 1B shows an example of a qualitative shift. In particular, this neuron shifts from a *resting* or off attractor state into an input-dominated attractor state we refer to as the *self-stabilized* state. In this attractor state, activation stays stably on (i.e., above 0) provided that the stimulus is present, and the strength of neural activation within this state can accurately mirror the strength of the input signal (see Figure 1B). If the input is removed for a significant period of time, however, the self-stabilized state becomes unstable and the system moves through another qualitative shift as it returns to the resting state. Indeed, there are four qualitative changes in the dynamics of this neural activation profile across the simulation shown in Figure 1B (see circled joints in the activation profile).

Conceptually, the self-stabilized state reflects a type of perceptual encoding: The shift into the self-stabilized state marks a detection decision, that is, the neuron has detected the presence of a reliable signal and it will remain in this state provided that the input remains reasonably robust. For instance, this neuron can stay in the self-stabilized state even when there are transient interruptions in the input signal as might occur when an infant moves her eyes briefly to look away from a stimulus and back again (for discussion, see Spencer, Perone, & Johnson, in press).

It turns out that the simple neuron simulated in Figure 1B can actually move into a third attractor state—the self-sustaining state—shown in Figure 1C.

In this simulation, the neural activation moves from the resting state into a state where activation stays stably on (above 0) even when the input is removed. Thus, there is only one qualitative shift in the behavior of the neuron in Figure 1C (see circled joint). Once the neuron detects the stimulus, it maintains an active representation of this detection decision for the duration of the simulation. The neuron is able to enter this attractor state because it has a relatively strong self-excitation parameter. Consequently, once stimulated, the neuron is able to keep excitation around, even when the external stimulus is turned off. This strong self-excitation is evident in the strength of activation in Figure 1C: At two points in this simulation, the strength of neural activation actually rises to a level that exceeds the input strength.

Just as the self-stabilized state provides a conceptual link to notions of perceptual encoding, the self-sustaining state captures a neurally plausible form of working memory (Fuster, 1994; Simmering et al., 2008; Spencer et al., 2007; Wang, 2001). We have shown, for example, that this basic form of sustained neural activity underlies the ability of children and adults to actively maintain information in spatial working memory during short-term delays (Spencer & Hund, 2003; Spencer et al., 2007). More recently, we have shown that this form of working memory also underlies the maintenance of nonspatial features such as color and orientation (Johnson, Spencer, Luck, & Schöner, 2008; Johnson, Spencer, & Schöner, 2008). And developmental changes in the ability to stably enter this working memory state can capture changes in the stability of spatial working memory over development (Schutte, Spencer, & Schöner, 2003; Simmering et al., 2008), the likelihood that infants and young children will perseverate in simple reaching tasks (Schutte et al., 2003; Spencer, Smith, & Thelen, 2001; Thelen, Schöner, Scheier, & Smith, 2001), as well as developmental changes in the capacity of the visual working memory system (Simmering & Spencer, 2008).

What determines whether a neuron or neural field is stabilized by input (Figure 1B) versus self-sustaining (Figure 1C)? The move between these two states requires a tiny tweak to the neuron's self-excitatory strength. With weaker self-excitation, the neuron enters the stabilized state; with stronger excitation, the neuron can be self-sustaining. This highlights that there is a deep connection between the notions of continuous change and transformational change within DST: A continuous and subtle change in the details of a neural system can produce a qualitative transformation in the attractor states the system moves into and out of in real time. Indeed, this tie between continuity and transformation becomes more intricate when one considers that the neural attractor states shown in Figures 1B and 1C are emergent and softly assembled from several factors—even in this simplest of cases. One can, for instance, move the neuron into the self-sustaining state (rather than the self-stabilized state) by boosting the strength of the input (for discussion, see Simmering et al., 2008).

Thus far, we have largely just asserted that the attractor states illustrated in Figures 1A to 1C are qualitatively different. One signature of the qualitative shifts are the joints in the neural activation profiles in Figures 1B and 1C that occur near an activation value of 0 as the system moves from the off state into a stable on state. In Figures 1D to 1F, we go one step further highlighting another key signature of behavior as a dynamical system moves through a qualitative transition—heightened variability near the transition point (van der Maas & Molenaar, 1992; Van Geert, 1998). In these simulations, we set the starting state of the neuron's activation just below 0, at 0, and just above 0, and then let neural activation change through time in the absence of input, but in the presence of a small bit of neural noise. What emerges are rather dramatic differences in how the linear system (Figure 1D), the self-stabilized neuron (Figure 1E), and the self-sustaining neuron (Figure 1F) behave.

As can be seen in Figure 1D, the linear system shows the same behavior regardless of its starting state—in the absence of input, neural activation shows exponential decay to a baseline level. This highlights that there is no special qualitative transition happening in this system as activation passes through the zero threshold. By contrast, Figure 1E behaves in a qualitatively different fashion once the initial activation level is greater than 0 (see right panel in Figure 1E). Now, self-excitation is strong enough that the system can hover in an on state temporarily, even in the absence of stimulus input. Note that if we were to compute the variability of neural activation across the simulations in this panel, the variance would be dramatically higher than in all the simulations shown in Figure 1D. The final set of simulations shown in Figure 1F shows the most dramatic case of heightened variability near a qualitative transition: When we set the neuron's initial activation state to 0 (see middle panel of Figure 1F), the system shows a roughly 50–50 chance of going into the off versus the on state.

Considered together, the simulations in Figure 1 illustrate what the concept of qualitative change means within DST. Three points are critical. First, the notion of qualitative change in DST is all about a change in the attractor states of a system—a shift from one stable state, through an instability, into a different attractor state. Second, you cannot judge a qualitative transition by its cover, that is, by just watching the system behave through time. Even simple systems with no qualitative changes in dynamics (a single attractor state) can exhibit complex patterns of behavior through time. To discover whether a qualitative transition has occurred, one must look deeper for signatures of transformational change such as high variance near transition points. Third, there is a deep connection between continuity and qualitative change within DST: qualitative transformations can arise from continuous changes in multiple aspects of the system, such as when a small change in self-excitation moves a neural system from a perceptual to a working memory state.

What About Qualitative Transitions in Development?

Although the dynamical behavior of the simple neuron in Figure 1 is interesting, it is a far cry from the types of developmental transitions typically studied in developmental science. What does this notion of qualitative change from DST buy us when thinking about qualitative *developmental* change?

Developmental changes in the dynamics of a system are often depicted as a shifting landscape of attractor wells. Figure 2 shows an early depiction of this notion from Waddington (1954), as well as an updated view from Muchisky, Gershkoff-Stowe, Cole, and Thelen (1996). In these figures, the organism is represented by the ball moving along a landscape. As each new valley opens up over development, qualitatively new states are available to the organism. For instance, the wells in Figure 2B capture different categories of action that emerge as infants shift from reaching, to crawling, to walking, and so on. Thus, the collection of wells at some moment in development captures the landscape of potential actions. And the depth of each well captures the stability of that particular action type (a deeper well is more stable).

Although this depiction of development is pervasive, there is an odd thing about depicting development in this manner. As deeper wells form as a function of skill acquisition, practice, consolidation, and so on, the system—the ball—will have a harder time getting out of the most stable states. This is a good thing if we are talking about the stability of an adult's walking pattern on bumpy ground, but it is not a good thing if we are talking about an adult's ability to flexibly shift from one stable action pattern (walking) to another (dancing). Skill involves stability (deep wells), but it also involves the ability to destabilize one pattern and move into another. Skill, therefore, involves qualitative change. How does the ball manage that nifty trick?

It turns out that the developmental landscape picture is a bit off in this regard. Although one can think of the ball getting kicked from one well to another to capture movement from one pattern to another, this does not effectively capture skilled behavior. Why? Empirical evidence shows that flexible, skilled behavior involves moving from one stable attractor state through an instability into another stable attractor state (see, e.g., Scholz & Kelso, 1989). This is precisely what our neuron did in Figure 1. Although one can think of this as having two wells and moving a ball back and forth, the more accurate picture is that the ball is in one well, *then that well*

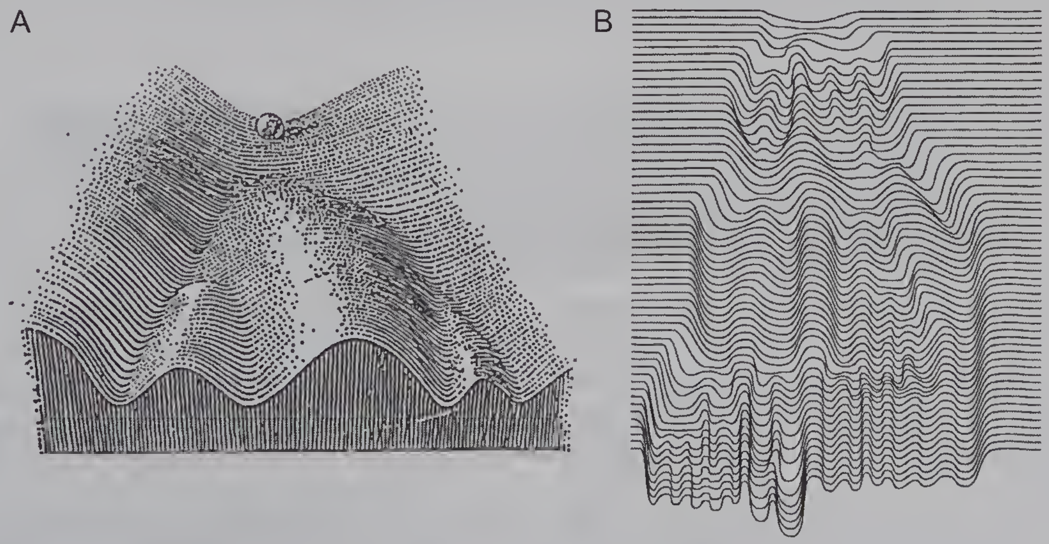

Figure 2. Depictions of developmental landscapes that invoke the concepts of dynamical systems theory: (A) epigenetic landscape described by Waddington (1954) and (B) developmental landscape described in Muchisky, Gershkoff-Stowe, Cole, and Thelen (1996).

disappears, and the ball rolls to a newly formed well nearby. By this view, attractor states are not sitting around; they are not competencies waiting to be tapped. Rather, attractors come and go in real time—the attractor landscape is dynamic and changing on the timescale of behavior (for related ideas, see Spivey, 2007).

It is important to note that the developmental landscapes in Figure 2 are not wrong; they are just limited. They provide a temporally averaged view of the real dynamics that are taking place. This can offer a useful survey of the terrain, but it can blur some important details, in this case, that the qualitative shifts that are taking place in development actually come and go and emerge and morph in real time.

How can we put the notion of real-time qualitative shifts (see Figure 1) together with a developmental landscape (see Figure 2)? Figure 3 shows one view of this integration, returning to our simple neural example from the previous section. The first thing we have done in this simulation is run it for many, many time steps—41,000 here compared to 400 in Figure 1. Thus, this figure is showing real-time changes in the behavior of our neuron (or neural field) over a timescale that might encompass a day or two of experience.

What is the neuron experiencing? Figure 3A shows the input to the neuron. The duration of the inputs vary to reflect some of the natural variations an infant might encounter as she moves from context to context. We have also simulated a simple form of developmental change. In particular, Figure 3B shows a slow, continuous (linear) change in the strength of self-excitation. This type of change might arise from a simple Hebbian process that strengthens synaptic connections that are repeatedly active (for related ideas, see Mareschal et al., 2007; Schutte et al., 2003; Simmering et al., 2008; Spencer, Dineva, & Schöner, in press).

As can be seen in Figure 3C, the combination of variations in input, random fluctuations in activation, and changes in self-excitation lead to the emergence of qualitatively new attractor states over the course of development in this simulation. At the start of the simulation, the neuron lives in a resting state (see the solid line above the neural activation profile). It shows some fluctuations up and down that mimic the input pattern, but it never enters the self-stabilized state.

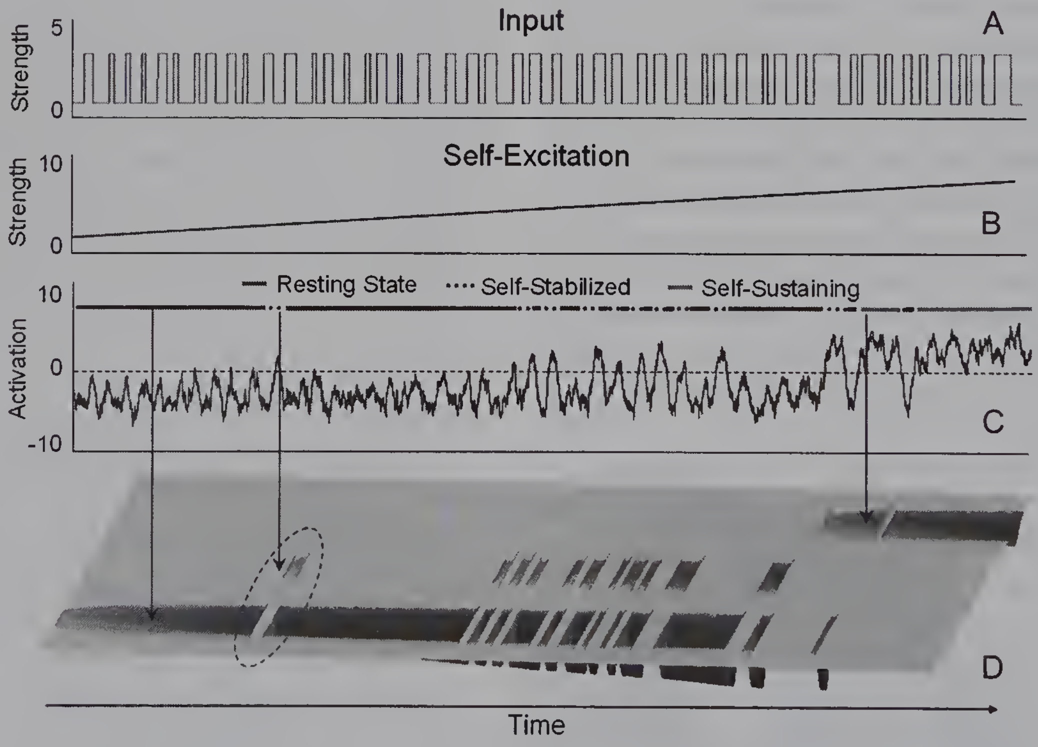

Figure 3. Simulation of a simple neural system in real time across a long time span to illustrate the integration of timescales within dynamical systems theory: (A) pattern of rectangular inputs over time, (B) linear increase in the neuron's self-excitation strength over time, (C) activation of the neuron over time, and (D) a developmental landscape constructed by mapping the attractor states shown above the activation profile in (C) onto a well diagram.
Note. Thick line (C) above the neural activation profile indicates the attractor state the neuron is in at each moment in time (solid line = resting state; dotted line = self-stabilized state; gray line = self-sustaining state). Arrows (D) show example of mapping for each attractor state. Circled transition marks the first qualitative transition in real time from the resting to the self-stabilized state. Depth of each well is scaled based on cumulative frequency of each attractor state over time.

As development unfolds, however, there is a qualitative shift in the neuron's behavior: It becomes more and more likely that the neuron will enter the self-stabilized state where it encodes the presence of a stimulus (see dotted line above the activation profile). Critically, although the neuron spends more time in the self-stabilized state, it is still moving into and out of this state through real time. Toward the end of this long simulation, the system first enters the self-sustaining or working memory state (see gray line above the activation profile). Again, we emphasize that this state first emerges in real time in the context of a particular stimulus input; however, over time, the system more reliably enters this state as self-excitation strengthens.

Figure 3D shows a developmental landscape that we created by transforming the categorization of the neuron's attractor states through time (see solid, dotted, and gray lines in Figure 3C) into a well diagram. Note that this landscape looks different from the images in Figure 2, in part, because time runs from left to right rather than from top to bottom. But there is also a more critical difference in how the wells change over time. Rather than having the emergence and deepening of new wells over time (Figure 2), *a qualitative change in the attractor layout occurs each time the neuron goes from one state to another in real time* (the first such occurrence is marked by the circle in Figure 3D). Over development, new states emerge in real time (first the self-stabilized state, then the self-sustaining state), these states become more stable (i.e., deeper), and the states are entered more reliably.

In summary, Figure 3 shows how qualitative shifts in behavior emerge in real time and cohere over the longer timescales of learning and development to give rise to the attractor states commonly depicted in developmental landscapes. Critically, Figure 3 clarifies how multiple timescales can be integrated within a developing system, making static wells dynamic in real time.

Implications of DST for Developmental Science

What are the implications of a dynamical systems view of qualitative change for developmental science? First, there is something very special about the notion of qualitative change within DST. This concept is about creating something new—a new attractor state—out of something old—the existing, diverse, and complex components that are newly assembled. It is about the emergence of new forms in real time as infants and children behave in real situations and how these new forms come to repeatedly cohere over learning and development.

Second, the integration of dynamics over multiple timescales highlights that developmental stability and change is always connected to the local details of behavior. Consequently, studying qualitative shifts in behavior over broad stretches of time—while often useful as a starting point—can sometimes reveal relatively little about the organization of behavior in real time. In this context, we agree with Kagan that claims of continuity across broad stretches of time that attempt to link infant behaviors with the behaviors of much older children must be treated as placeholders—approximations that should always be viewed with a critical eye. Importantly, however, this same critique applies whether we extend the arrow of time forward in development from infancy to childhood or backward in development from infancy to the prenatal period and purported biological (or evolutionary) predispositions (Spelke, 1998; Spelke & Kinzler, 2007). Approximations that extend far in both temporal directions should be treated with much more care in our science (Spencer, Blumberg, et al., in press).

The third implication of a dynamical systems view is that understanding qualitative developmental shifts is extremely complicated. One cannot just observe the local behavior of a system and extract the attractor states around which behavior is organized. Rather, one must look for the unique signatures that separate one state from another. And given that attractor states are softly assembled and multiply determined, it can be difficult to understand why they come and go, especially when the components that make up behavior are linked in nonobvious ways. These behavioral realities—which have been born out in many well-studied empirical examples—provide even more reason to think about development locally and be highly dubious of claims of long-term continuity, nativist or otherwise (see Spencer, Blumberg, et al., in press).

In conclusion, the challenge of a dynamical systems view is that to understand development, we must understand how the dynamics of a system change over multiple timescales, how qualitatively new attractor states emerge in real time, and how those attractors become more accessible, more stable, and more tuned to the particulars of the situation over development. Thus, we agree with a central theme of Kagan's (2008) article: Qualitative shifts in development occur, and they should be defended because they are fundamental to what emergence over development is all about. But qualitative change should not be put in opposition to gradual, continuous change as Kagan's article implies. Continuity and change go hand in hand. We think DST offers a firm defense of qualitative development, a formal framework for understanding the link between qualitative development and continuity, and a charge to push our understanding of development to the more local timescale where emergence and continuity come together to truly create something new out of something old.

In Defense of Change Processes

Karen E. Adolph

Scott R. Robinson
University of Iowa

Nativist and constructivist approaches to the study of development share a common emphasis on characterizing beginning and end states in development. This focus has highlighted the question of preservation and transformation—whether core aspects of the adult end state are present in the earliest manifestations during infancy. In contrast, a developmental systems approach emphasizes the process of developmental change. This perspective eschews the notions of objective starting and ending points in a developmental progression and rejects the idea that any particular factor should enjoy a privileged status in explaining developmental change. Using examples from motor development and animal behavior, we show how a developmental systems framework can avoid the pitfalls of the long and contentious debate about continuity versus qualitative change.

Continuity and Qualitative Change

Every developmental researcher agrees that the primary goal of developmental psychology is to understand development. As described in Kagan (2008), a popular approach to the problem of understanding development is to characterize beginning and end states in a developmental progression and to determine whether important structural and functional features in the initial incarnation are present in the later, adultlike appearance of the skill (Carey, 1991; Pinker, 1984; Spelke & Kinzler, 2007). A variant of this "stable state" approach to development is to document multiple stages between beginning and end states and to determine critical similarities and differences among them (Piaget, 1954). The focus on origins, stages, and end states has led researchers from nativist and constructivist frameworks to engage in a long and furious debate about the preservation versus transformation of earlier structures and functions in later, more mature forms. For these researchers, the tension between continuity and qualitative change remains a central issue for understanding development.

In the domain of conceptual development, Kagan points out that arguments for continuity between critical aspects of infants' and adults' conceptual knowledge are based largely on inferences drawn from a relatively lean database: the accumulated duration of young infants' looking times to unexpected visual displays. Based on his discomfort in ascribing conceptual knowledge to young infants based on changes in looking times, Kagan suggests that the notion of qualitative changes in development remains viable. He is in good company: Other researchers have criticized looking times as a basis for inference about infants' conceptual abilities (Bogartz, Shinsky, & Schilling, 2000; Thomas & Gilmore, 2004) and have thus argued in defense of qualitative differences between infant and adult forms in conceptual development.

Ironically, regardless of whether researchers locate themselves on the continuity or discontinuity side of the debate, the focus on characterizing beginning and end states has resulted in a shortage of research on the process of developmental change. The literature is filled with exciting lo-and-behold studies of the earliest manifestations of infants' abilities. Journals and textbooks abound with before and after snapshots of children's remarkably inept behaviors at Time 1 and more mature behaviors at Time 2. However, developmental scientists know surprisingly little about the process of development. Even Piaget's stages—the best-known characterization of children's mental structures—are so exasperatingly bereft of detailed change processes that Klahr (1982) referred to assimilation and accommodation as the "Batman and Robin" of developmental psychology (p. 80). Missing are accounts of developmental change processes.

An alternative, developmental systems framework (Gottlieb, 2007; Oyama, Griffith, & Gray, 2001; Thelen & Smith, 1994) may prove more useful for meeting the goal of understanding development. A developmental systems view sidesteps the debate over continuity and qualitative change—at least as it is formulated with reference to beginning and end states. Periods of relative stability are considered only as benchmarks because stable periods at the ends of a progression may be pushed ever outward or shown to be unstable under less favorable conditions. Common features between earlier and later appearing skills are not accorded privileged developmental status because mature forms are the result of multiple factors, each of which must be at a particular level of readiness. Researchers accept as a matter of course that some structures and functions are preserved (more or less), and some are not.

Most important, a developmental systems framework is concerned with process rather than end products. The focus is shifted from characterizing children's abilities at Time 1 and Time 2 to characterizing the trajectory between the periods of relative stability and the underlying mechanisms of change that shape the developmental path. Arguments about continuity and discontinuity are more likely to arise around the shape of the developmental trajectory, rather than around the preservation of structural or functional features from one time to the next.

Kagan focused on cognitive development and the problem of drawing strong inferences about conceptual structures from small changes in infants' looking times. However, the ideas raised in the article have broad implications for understanding developmental change in other domains. We expand on Kagan's ideas, drawing on evidence from motor development and animal behavior to illustrate our points.

Beginning and End States

Although the theoretical positions of nativism, as exemplified by the work of Spelke and her colleagues (Spelke & Newport, 1998), and constructivism, as exemplified by the work of Piaget and as espoused by Kagan in his target article, are diametrically opposed in terms of the continuity/qualitative change debate, they share a common perspective in discussing development in terms of preservation and transformation. Perhaps the debate is a natural outgrowth of comparing infants to older children or adults: Comparison of performance at Time 1 and Time 2 naturally leads to questions about what remains unchanged and what differs between the two times.

Moreover, both nativist and constructivist traditions share a tendency to reify the beginning and end states in a developmental progression, especially when the ages are sampled from infancy and adulthood. The earliest times at which a particular experimental method can be applied are often interpreted as the starting point for development of the phenomenon, and infants' success in the task is interpreted as core knowledge (Spelke & Kinzler, 2007) or the primary repertoire (cf. Sporns & Edelman, 1993). An arms race has emerged in this game, with methodological advances allowing researchers to tout infants' abilities at earlier and earlier ages.

The assumption of an initial condition and a mature end state in development is not limited to conceptual knowledge, grammar, or other cognitive abilities. In motor development, where structure and form can be observed directly rather than inferred from outward behaviors such as looking times, many researchers also have assumed beginning and end states in development. Adult walking, for example, can be characterized by alternating movements of the limbs within a girdle (the two legs in humans and birds and the forelimbs and hindlimbs in quadrupeds) and by alternating flexor and extensor muscle activation within each limb. Long before infants can walk, however, they can move their legs in alternation. When newborn infants are held upright, they alternate their legs in slow marching movements; while lying on their backs, infants spontaneously kick their legs using many of the same alternating coordination patterns; and ultrasound recordings confirm alternating leg movements in the human fetus (Suzuki & Yamamuro, 1985; Thelen & Fisher, 1982). Before birth or hatching, the rat fetus and chick embryo display alternating leg movements during spontaneous and pharmacologically induced motor activity (Bekoff, 1992; Brumley & Robinson, 2005). Even more dramatic, both adult and infant animal preparations can generate alternating limb activity with spinal cord circuitry alone. Moreover, dedicated neural structures in the spinal cord—termed "central pattern generators" (CPGs)—have a distinct window of development. In the rat, CPGs begin to produce bursts of alternating activity in the spinal nerves that project to limb muscles 3–4 days before birth.

The presence of alternating coordination patterns in the legs and spinal cords of infants and fetuses has led many prominent researchers in motor development to argue that the foundations of locomotion are established prenatally, presumably when CPGs become active (Grillner & Wallen, 2004; Prechtl, 1997). Similarly, Spelke and Newport (1998) in their influential *Handbook* chapter interpreted the early coordination patterns as "inborn, foundational action capacities that persist over development and are common across a great range of animal species" and that "provide the core of humans' ability to locomote" (p. 278). According to this stable state view of motor development, the basic locomotor pattern may be masked at some points in development and later modulated by perceptual feedback and experience, but it remains unchanged in its fundamental form and organization (Grillner & Wallen, 2004).

Change Processes

Regardless of whether researchers lean toward nativism or constructivism, continuity or qualitative change, developmental psychology suffers from a lack of focus on change processes. One suggested solution is that researchers should take seriously the problem of describing the developmental path from Time 1 to Time 2 (Siegler, 2006; Vygotsky, 1978). How does infants' differential looking at an impossible physical event become elaborated or transformed into adults' understanding of physical constraints on objects? How does infants' alternating leg movements develop into running across a cluttered living room floor? A developmental systems approach urges researchers to embrace the challenge of explaining change processes and advocates that they take the idea one step further by rejecting the notion of a privileged factor that is core or foundational in engendering development and by rejecting the assumption of an initial starting point or a mature end state. According to the developmental systems perspective, there are no developmentally special Time 1s and Time 2s. Process is all there is. As stated so eloquently by Hutton (1795) when explaining the geological history of the earth, "we find no vestige of a beginning, no prospect of an end" (p. 80).

Starting and ending points are arbitrary. The rich motor, sensory, and learning abilities of the fetus should render suspect any claims about the primacy of birth in defining initial conditions in development. Other developmental benchmarks such as conception, puberty, and death are salient but not privileged starting or ending points in development. Environmental, organismic, physiological, and genetic factors can exert their influences beyond these boundaries.

Developmental systems researchers address the question of developmental origins by examining the multicausal, multidimensional, and temporally complex details of change processes. For example, it may seem reasonable to locate the developmental roots of sex-typed behavior (e.g., sexual receptivity, aggression) in puberty when the testes and ovaries produce hormones at elevated levels. However, experiments with rodents and other animals that bear multiple offspring indicate that the initial starting point for sex-typical behavior in adulthood can occur long before puberty, before birth, and even before conception. The roots of sex-typed behavior can be located in the rodent dam or in her mother or her mother before her. Female gerbils exhibit masculinized behaviors as adults (display more aggression, more mounting, less receptive lordosis, etc.) if they gestate in a prenatal environment predominated by male fetuses where they are exposed to higher levels of male androgens during sensitive periods of brain development (Ryan & Vandenbergh, 2002). They also exhibit masculinized hormonal development that biases them to produce male-dominated litters themselves, perpetuating the effects of prenatal masculinization across generations (Clark, Karpiuk, & Galef, 1993). Moreover, hormonal exposure is not a privileged factor in sex-typed development. Other effects on sex-typed behaviors can be nonobvious but equally important: Different amounts of maternal licking of rat pups' anogenital region (an important part of maternal care) can bias and accentuate tendencies to express male- or female-typed behaviors later in life (Moore, 1995).

Returning to the example of alternating leg movements in the development of walking, what are we to conclude from the compelling demonstrations of coordinated alternation in neonates and fetuses, the dedicated neural circuitry that seems to underlie the coordination pattern, and the striking similarity between the alternating coordination patterns in infants and adults? From a stable state perspective, the alternating pattern represents a core capacity in adult walking and reveals continuity between beginning and end states (Spelke & Newport, 1998). The developmental systems perspective offers a different interpretation: The activation of a CPG is not a privileged starting point for the development of locomotion, the alternating pattern is no more "core" than the multitude of factors that contribute to the development of walking, and there is no objective end point for adult gait.

The activation of a CPG is not a privileged starting point for the development of walking because alternating bursts of activity in the ventral roots of spinal nerves is not a discrete developmental event. As with all phenomena, the alternating pattern has a developmental history. In the rat fetus, days before spinal nerves show the alternating pattern, the same neural circuitry generates synchronized bursts of activity that result in spontaneous limb movements that are not alternating (Bekoff, 1992). The different patterns likely result from developmental changes in the inhibitory neurotransmitter systems. Gamma-aminobutyric acid (GABA) and glycine, the two most important inhibitory neurotransmitters in the central nervous system, are excitatory rather than inhibitory in the spinal cord of younger fetuses.

Moreover, after the alternating pattern becomes available, it is not obligatory. Human infants spontaneously and deliberately move their legs in a variety of coordination patterns while kicking, crawling, and upright throughout the 1st year. Coordination patterns are plastic and can be flexibly adapted to local conditions. For example, tying rat fetuses' hind legs together with a tiny elastic string shifts the spontaneous pattern of interlimb coordination from alternating to synchronous, and the new pattern is maintained after the string is cut (Robinson, 2005). A similar manipulation shifts the alternating pattern to a synchronous one in human infants (Thelen, 1994).

Alternating leg movements are not a privileged developmental factor in the acquisition of walking. The alternating pattern is only one of the many critical factors that must be in place for infants to walk. The list also includes balance control, muscle strength, appropriate body proportions, sensitivity to visual flow, the ability to detect affordances for upright locomotion, and the motivation to go somewhere (Thelen & Smith, 1994). Each of these factors shares some commonalities and some differences with adult walking, and each has a different developmental time course. For example, although alternation is a key aspect of adult gait in humans, rats, and cats, many mammals that display the alternating pattern during fetal and infancy periods do not alternate their legs as adults (Eilam, 1997). Hopping and bounding are the mature gait patterns of kangaroos, rabbits, and desert rodents such as gerbils, jerboas, and kangaroo rats. More important, the transition from alternation to synchronous hopping occurs postnatally, coincident with rapid changes in leg morphology. From the developmental systems perspective, the goal of developmental analysis is to understand the paths, interrelations, and causal mechanisms of the various time course of each contributing factor.

Defining an end point to development may be an equally difficult enterprise. Structures and functions assumed to be stable features of the adult skill may turn out to be stable only under certain rearing or testing conditions. The structure of adult walking, for example, has been characterized in exquisite detail in terms of inter- and intralimb timing, joint angles, the coordination of flexor and extensor muscle activation, and the dynamic forces produced at each point in the step cycle. However, different rearing and testing conditions can lead to very different end points: A family of adult siblings in Turkey crawl on their hands and feet rather than walk, although walking was physically possible (Humphrey, Skoyles, & Keynes, 2005). A dog born without forelegs developed smooth and functional bipedal locomotion (Stringfellow, 2007). A thousand years of foot binding in China resulted in billions of girls with altered gait patterns to accommodate balance and propulsion on three-inch long feet (Adolph, Karasik, & Tamis-LeMonda, in press). Women in western Kenya have altered the dynamic characteristics of their gait patterns so as to carry tremendous loads on their heads (up to 70% of body weight) with reduced energetic costs (Heglund, Willems, Penta, & Cavagna, 1995). Endurance running is so advanced in the Tarahumaran Indians of the American Southwest that they regularly run the distance of six modern marathons in 1–2 days time (Devine, 1985). Such individual and cultural variations in developmental end points are windows on developmental process and are not as readily accommodated by presumptions of species-typical developmental patterns leading to normal adult behavior.

Methodological Challenges and Conceptual Payoffs

As Kagan reminds us, conclusions about development are only as good as the data. Developmental research has suffered from overreliance on particular experimental paradigms, such as looking time in infants' conceptual development. Strong interpretations about children's knowledge or skills warrant rich data sets derived from convergent behavioral and physiological measures obtained in multiple paradigms. Robust conclusions about the process of change require robust sources of evidence, including adequate sampling to observe change as it occurs.

One strategy for choosing appropriate developmental measures is to use methods that can be applied across a range of ages. The problem with this strategy, as Kagan points out, is that the same measure may reflect different functions or underlying mechanisms at different ages. Kagan suggests that this problem can be avoided by measuring variables at different levels of analysis, presumably closer to the underlying neural and physiological mechanisms governing the response. Physiological measures, such as brain imaging, heart rate, skin conductance, and electromyographic recording, can be sampled across a broad range of ages.

An important caveat, however, is that measurement of variables at lower levels of analysis does not ensure relevance for understanding processes of developmental change. Changes in looking time or any other behavioral measure are accompanied by dramatic changes in body dimensions, physiology, neuroanatomy, neurochemistry, and the growth, interaction, and functioning of cells. These changes are parallel to and deeply interactive with changes in behavior; the direction of causal influence points up and down levels of analysis. Neural, motor, and sensory experiences play dramatic roles in shaping the course of brain development. A developmental systems perspective is particularly helpful from this standpoint because the emphasis on multicausality and multiple levels of analysis emphasizes the need for multiple convergent lines of evidence for characterizing any developing behavior.

Ultimately, we may find no substitutes, only supplements, for direct behavioral assessments, and so the selection of age-appropriate behavioral tasks will remain an important consideration in planning developmental research. In much of the current developmental research, behavioral measures have become more specific and restricted. Kagan points out that total looking time ignores the duration of looking bouts, the number of shifts of attention, the location of eye gaze, and other measures of visual exploration that can be captured from video and eye-tracking recordings. Highly simplified tasks such as change in total duration of looking time facilitate the ease of measuring infant responses but fail to take advantage of infants' rich repertoire of behaviors (e.g., facial expressions, reaching, postural and locomotor responses, social expressions and interactions) that are likely to prove informative when viewed as additional, convergent sources of evidence about infants' perceptions, emotions, and cognitive abilities. Overreliance on a single paradigm may present an overly restricted picture of the diversity of infants' abilities.

A consequence of shifting the focus from identifying beginning and end states to understanding processes of change is choosing appropriate measures and regimes for sampling behavior across development. Surprisingly, the issue of how to make an informed choice about the rate of sampling developmental change has received little attention in developmental psychology. The legacy of nativist and constructivist traditions is that infrequent sampling is viewed as sufficient to identify the major stages and transformations that occur in the course of development. But infrequent sampling can grossly distort patterns of variability and the overall shape of change in the path of development.

Using a data set of infant motor skills sampled daily during the first 18 months and resampled to simulate alternative regimes ranging from 2 to 31 days, we have reported that sampling at rates as frequent as weekly can seriously underestimate the amount of variability relative to daily sampling of motor skills (Adolph, Robinson, Young, & Gill-Alvarez, 2008). Sensitivity to variability is reduced as an inverse power function of the rate of sampling, such that skills that fluctuate between expression and nonexpression 10 or 20 times before achieving a period of stable occurrence erroneously look like single stage-like transformations when indexed weekly or monthly. In fact, 84% of the 261 data sets were characterized by variable trajectories when sampled daily, but 93% appeared to show a single stage-like appearance of the skill when sampled monthly. Estimates of the day of onset of a skill were similarly affected, with errors up to 109 days compared to daily sampling. If developmentalists are to take seriously the challenge of understanding processes of developmental change, then fresh looks at the shape of developmental change will require careful consideration of our methods and rates of collecting developmental data.

In summary, the developing child is a complex and interactive system. The way we view development therefore should transcend simple conceptions of preservation and transformation to characterize patterns and processes of change. We agree with Thelen and Smith (1998) that important progress can be made in understanding change processes if researchers abandon the old dualities such as continuity versus qualitative change and shift their focus to how the developing system works. The developmental systems approach holds additional promise. With a focus on describing the multilayered, multicausal path of development, researchers may gain a better understanding of underlying change mechanisms.

Methodological and Epistemological Issues in the Interpretation of Infant Cognitive Development

Ulrich Müller and Gerald Giesbrecht
University of Victoria

This commentary on J. Kagan (2008) addresses 2 issues. The first concerns the importance of studying developmental sequences and processes of change. The second concerns epistemological differences between contemporary neonativist approaches and classical theories of development. The commentary argues that classical theories of infant cognition and contemporary neonativist theories fundamentally differ in terms of how they conceptualize the workings of the mind. These differences affect the meaning of terms such as representation and reasoning. Also discussed are implications of epistemological differences for developmental explanations. The commentary concludes that epistemological differences must be articulated more fully in order to improve understanding of different theories and in order to evaluate the relative merits and shortcomings of those theories.

Kagan (2008) joins the chorus of recent critics who have argued that the rich interpretation of infant looking-time data is not warranted (e.g., Bremner & Mareschal, 2004; Cohen & Cashon, 2006; Newcombe, 2002; Rakison, 2007). Kagan challenges the rich interpretation of looking-time data on two grounds. First, he points out that the evidential basis for a rich interpretation is not as clear cut as one might wish. This is due to methodological problems with the interpretation of looking time data as well as the fact that conclusions about infant cognition rest on looking-time data only. To put the interpretation of findings on more solid ground, Kagan makes valuable suggestions regarding the use of a greater variety of measures in studies of infant cognition. The second challenge follows from the epistemological distinction between different knowing levels. Kagan distinguishes between a perceptual-sensorimotor level of knowing ("schemata") and a conceptual level of knowing ("semantic form"). He argues that findings generated in the looking-time (i.e., violation of expectation) paradigm do not require a rich interpretation but are consistent with a perceptual-level explanation. Kagan provides numerous excellent examples that we think convincingly drive this message home.

In our commentary, we address two issues. The first issue concerns the importance of studying developmental sequences and processes of change. The second issue concerns some epistemological differences between contemporary neonativist approaches and classical theories of development. We are skeptical that methodological refinements alone will settle the issue concerning the interpretation of findings from looking time experiments (and of infant cognition in general). This is because theories operate within different epistemological frameworks that make different assumptions about the workings of the mind. We will draw mostly on work by Baillargeon (on the neonativist side) and Piaget (on the classical side) to highlight these differences, but we could as well have used other theorists such as, on the one hand, Wynn and Leslie, and on the other hand, Baldwin, Stern, Werner, and Vygotsky.

The Importance of Studying Developmental Sequences and Processes of Change

An important point raised by Kagan (2008; see also Werner, 1957) is that similar behaviors and performances may be mediated by different cognitive operations or mechanisms. Despite similarities in performance over time, the underlying process by which outcomes are achieved may vary dramatically (Siegler, 1995), and these variations are indicative of similarities and differences in the cognitive abilities at different developmental levels. One way of disambiguating the cognitive basis of infants' performance is to place the performance at earlier developmental levels in the context of an extended developmental sequence and to interpret the initial steps in this sequence in the light of the last steps. Piaget terms

this the method of recurrence, which consists "in extending in the opposite direction the lines of the genetic process revealed by the study of the last stages. The ground for interpretations relating to the point of departure of a concept can only be shown a posteriori by the probability of the explanation based on the total evolution of that concept" (Piaget, 1937/1954, p. 221).

Studies of developmental sequences assist in determining whether a particular behavior at an earlier point in time is a precursor or prerequisite of behavior at a later point (Campbell & Richie, 1983). Furthermore, by designing studies of developmental sequences in a way that captures the processes involved in the transformation of abilities over time, constraints can be placed on the interpretation of the cognitive basis of behavior because understanding the mechanisms of change helps in determining the cognitive organization that characterizes behavior at different levels of development.

Epistemological Issues: It Is Not Just About What Is Innate Versus Learned

Neonativists (Baillargeon, 2008; Spelke, 1998) place their findings in the context of long-standing controversy between rationalism and empiricism. We are told that rationalist philosophers such as Descartes and Leibniz endorsed innate ideas, whereas empiricist philosophers such as Locke, Hume, and Mill rejected innate ideas and explained the acquisition of knowledge in terms of experience and domain-general processes operating on experience (Baillargeon, 2008). Contemporary findings are then claimed to shed light on this old epistemological controversy (Spelke, 1998). Leaving aside the issue that the epistemological controversy concerns the sources and techniques by means of which claims to knowledge are to be justified (which is a matter quite different from identifying the developmental origins of knowledge), a more careful reading of these philosophers suggests that their claims about innate ideas are more complex and cannot that easily be divided along the lines of nativism versus learning (Gorham, 2002; Greenlee, 1972; Saville, 1972). For example, Locke's theory of language does not refute innate ideas and is, in terms of theoretical assumptions, surprisingly similar to Pinker's theory of language (Proudfoot, in press). Overlooked in the fixation on the innate versus learning issue are deeper epistemological differences in terms of how the working of the mind is conceptualized in different theories. Next, we briefly illustrate some of these differences and show how they affect the meaning of terms such as representation and reasoning. Finally, we suggest that these epistemological differences have implications for (a) what different theories consider to be in need of explanation and (b) what form such explanations should take (Overton, 2006; Samuels, 2002).

Contemporary neonativism is based on a causal representational or mechanist theory of meaning, which itself is rooted in the empiricist tradition (Goldberg, 1991; McDonough, 1989). According to such theories, meaning and behavior are explained through internal representations that mediate between input and output. These representations are causally produced by input (e.g., perceptual information) and, in turn, effect some output (e.g., bodily movements). One's mental contents, or ideas, are just the effects of stimuli external to the mind and the mechanical operations or computations triggered by those stimuli. In this sense, these representations are not intentional, and there is no active agent producing them. Representations become entities that take on a life of their own. As a result, the "person as agent becomes superfluous" (Judge, 1985, p. 51).

Arguably, Baillargeon's (2008) account of infants' physical reasoning instantiates a causal (empiricist) representational theory of meaning. According to Baillargeon, infants are born with the principle of persistence. This principle holds that "objects persist, as they are, in time and space" (Baillargeon, 2008, p. 3). This principle is part of a physical reasoning system, which is characterized "as an abstract computational system designed to monitor events as they unfold and to interpret and predict their outcomes" (Baillargeon, 2008, p. 3). When infants observe a pertinent event, the physical reasoning system is activated and it builds a representation of the event. For example, "while watching a red ball being alternately lowered behind and lifted above a screen, infants would represent the information 'inert closed object being alternately lowered behind and lifted above inert closed object'" (Baillargeon, 2008, p. 4). The representation becomes enriched as, with experience, infants include—through a process of association—more and more information in the representation of the event.

Baillargeon's account of the development of physical reasoning exemplifies a causal representational theory of meaning because the representations of events are triggered by some input and run through some computations that are performed by the physical reasoning system, which then produces an output (e.g., increased attention to the physically impossible event). The representations are unintentional in the same way as, say, the patellar reflex: It is not the infant who is doing the reasoning but some device inside the infant's head computes the representation. The computation and representation are happening to the infant; the infant is herself passive. For that reason, it is somewhat a misnomer to speak in this instance of "infant reasoning" because these processes are subpersonal and performed by some device, as Baillargeon (2004, p. 422) explicitly states: "It seems very unlikely that infants possess explicit beliefs about anything. What they do possess is an abstract computational system, a physical reasoning system that monitors physical events and flags those that do not unfold as expected for further scrutiny." In this sense, these processes might also be likened to, for example, computational processes that are performed by the visual system to achieve perceptual constancies.

To highlight the importance of epistemological frameworks, let us contrast Baillargeon's empiricist theory with Piaget's constructivist sensorimotor theory. Somewhat ironically, Baillargeon (2008) classifies Piaget as an empiricist, even though Piaget's critical stance toward empiricist theories should be well known (Piaget & Inhelder, 1969). For Piaget (1936/1963), the basic functions with which the infant interacts with the world are assimilation and accommodation. Piaget's notion of assimilation, at the psychological level, particularly highlights the active, intentional nature of the mind. Specifically, assimilatory schemes (e.g., grasping, pushing) comprise a need and are directed toward specific goals; that is, they refer to the particular elements or objects toward which human activity, and consciousness more specifically, is directed. By assimilating objects to preexisting behavioral or cognitive schemes, the individual confers some kind of meaning on these, whether it be simply of a functional sort or (later on) more abstract in nature. Accommodation, on the other hand, is the aspect of the activity that provides the particular content for assimilation. Piaget holds that by accommodating to the environment, an organism's existing schemes are differentiated and modified. To illustrate, by assimilating different objects to the grasping scheme, these objects acquire the functional meaning "graspable" while at the same time, the infant learns to adjust her grasp to the specifics of different objects (accommodation). Meaning is created by the infant casting a web of intentionality onto the world. In fact, Piaget's action-based approach to knowledge acquisition and the working of the mind was designed to overcome the problems inherent in empiricist causal representational theories of mind such as Baillargeon's (see Bickhard, 1999; Bickhard & Terveen, 1995).

Even our necessarily cursory discussion of this matter should make it clear that there are fundamental differences in the way in which contemporary neonativist theories (exemplified by Baillargeon's theory) and classical approaches (exemplified here by Piaget's theory) conceptualize the working of the mind. Basically, in the tradition of empiricist causal representational theories, Baillargeon's theory conceptualizes the mind as passive and nonintentional, whereas Piaget's theory conceptualizes the mind as active and intentional (for a more detailed treatment, see Müller & Newman, 2008; Müller, Sokol, & Overton, 1998).

It is not surprising that, given these different epistemological frameworks, the same terms take on different meanings in Baillargeon's and Piaget's theories. Whereas for Baillargeon, representation is the effect of some input, this cannot be the case for Piaget. Furthermore, Piaget (1936/1963, pp. 242–243) distinguishes between two different meanings of representation. In one meaning, Piaget (1936/1963, p. 242) refers to representation as nonsymbolic meaning. This type of representation is evident in "the capacity to confer upon things a meaning before the action which this meaning permits. . . . The act of looking under a shawl for a shoe in order to strike it with a piece of wood (Obs. 129) is the prototype of this behavior pattern." Representation in the sense of nonsymbolic meaning is thus evident in anticipation, but nonsymbolic meaning can be traced back to the very beginning of mental life (Piaget, 1936/1963, p. 38).

In the second meaning, representation refers to the capacity to use symbols and signs to evoke an absent object. To our knowledge, neonativist have not yet spelled out whether the representations their experiments unveil are located at the level of nonsymbolic meanings or symbolic-representational meanings. Part of the reason for this is, we suspect, that Piaget's and neonativist theories operate with fundamentally different concepts of representation, whereas within Piaget's theory, it makes sense to distinguish between nonsymbolic and symbolic-representational meaning, this distinction does not make much sense when representation is conceived as an operation of a computational device.

Reasoning is another term that takes on a very different meaning in Baillargeon's and Piaget's theories. As we have seen, for Baillargeon (2008) reasoning is a subpersonal process that runs off in a computational device. Piaget (1936/1963, pp. 239–240, 267–268), too, wrote about reasoning in infancy. Specifically, he drew a functional analogy between particular sensorimotor action patterns that subordinate one scheme as means (e.g., pushing away an obstacle) to another scheme (e.g., grasping an object) as end and the subordination of premises to conclusions at the level of verbal intelligence.

Piaget thus ascribes reasoning to infants when their actions put objects into a hierarchical relation. For Piaget, sensorimotor "reasoning" is thus not a subpersonal process but rather indicated by a certain level of complexity of infants' actions in pursuit of their goals. Of course, it should be noted that for Piaget (1936/1963, p. 240; 1947/1950, pp. 220–223), sensorimotor reasoning is qualitatively different from reasoning on the symbolic, reflective plane. In fact, Piaget uses some of the same criteria to distinguish practical sensorimotor intelligence from reflective, symbolic intelligence as Kagan does for demarcating schematic knowledge and semantic-conceptual knowledge.

Epistemological frameworks have implications for the types of things that different theories consider to be in need of explanation. In Baillargeon's theory, the infant is essentially a spectator, or "couch potato," as Willatts (1997) termed it, who takes a reflective, contemplative attitude to the events she is presented with, reasons about them, and searches for explanations of unexpected events (Baillargeon, 2008). What Baillargeon's (2008) theory aims to explain, then, is how infants initially impoverished representations become gradually richer. Baillargeon's view of the infant differs markedly from that of classical theories, which argue that the contemplative attitude is secondary and develops out of a pragmatic, unreflective attitude. Objects are originally perceived as *things of action* (Werner & Kaplan, 1963): They are imbued with affect, closely tied to the current situation and the satisfaction of immediate needs. As a result, classical theories of development aim at explaining how the infant gradually comes to distance herself and detach meaning from the immediate situation such that the infant is no longer dominated by immediate impressions and impulses (Piaget, 1936/1963; Vygotsky, 1933/1978; Werner & Kaplan, 1963). This notion of distancing is nicely captured in the following remarks by Gehlen (1940/1988):

> The things in our world thus have the essentially human character of *acquired neutrality*. This is not the indifference toward anything that does not appeal directly to instincts, as is the case in the environments of the higher animals. In contrast, the things around us are thoroughly known and "worked through," but remain "undecided" for the most part, available for interaction at any time. This is how man masters the overwhelming barrage of impressions, this is how he obtains relief: He *actively* "checkmates" *the forcefulness of the world's impressions, making the world potentially available at any time.* (pp. 162–163, emphases in original)

It is difficult to see how the notion of distancing could have a place in Baillargeon's theory. Given that representations are computed and interpreted by a physical reasoning system, there is no place for a distancing process. The objectivity of the world is built into the modular device and, as such, vanishes.

Finally, it should come as no surprise that epistemological differences affect the form that explanations take in different theories (for a detailed discussion, see Overton, 2006). Although in Baillargeon's (2008) theory, explanations invoke quantitative changes in the efficiency of computations and the type of information that is processed, classical theories (e.g., Piaget, 1936/1963; Werner, 1957) invoke processes such as differentiation and integration as explanations of the distancing processes.

Conclusions

Kagan makes numerous excellent points and provides several excellent suggestions that, if heeded, will undoubtedly help provide the field of infancy research with a better evidential basis. However, we are skeptical that the controversy over the interpretations of empirical findings on infant cognition will be settled by more methodological sophistication alone. In fact, it is not clear to us that the distinction between different knowing levels suggested by Kagan could even be meaningfully applied to the computational devices outlined in neonativist theories. Furthermore, deeper lying epistemological differences color the meaning of the terms being used, the goal of the explanations, and the very types of explanations thought. We believe that more effort must be put into articulating these epistemological differences. Only in this way will it be apparent that terms (e.g., representation) have meanings in one theory that are very different from their meanings in another theory. Eventually, such effort will also help us to better understand and evaluate the merits and shortcomings of different theories.

Automatic Activation of Adolescents' Peer-Relational Schemas: Evidence From Priming With Facial Identity

Lauri Nummenmaa
MRC Cognition and Brain Sciences Unit and University of Tampere

Kätlin Peets
University of Turku

Christina Salmivalli
University of Turku and University of Stavanger

This study provides experimental evidence for automatic, relationship-specific social information processing in 13-year-old adolescents. Photographs of participants' liked, disliked, and unknown peers were used as primes in an affective priming task with happy and angry facial expression probes and in a hypothetical vignette task. For the affective priming, reaction times were faster for congruent than for incongruent prime–probe pairs when the prime visibility was high and the prime–probe stimulus onset asynchrony was long. In the vignette task, participants attributed more hostility toward the protagonist, experienced more anger, and were more likely to retaliate when the disliked peer served as a prime. It is concluded that peer-relational schemas and related affect are activated automatically upon perception of a peer.

The social information processing (SIP) model (Dodge, 1986; reformulated by Crick & Dodge, 1994), has been one of the most influential theoretical models used to explain the behaviors of children and adolescents. According to the model, children enter social situations with relatively stable knowledge structures, such as social schemas, that guide online processing of situational cues. The online processing involves encoding and interpretation of cues, clarification of goals for the situation, response access, and finally, response decision. The present study was designed to address three issues that have received extensive attention in the literature but have rarely been studied empirically: (a) automaticity, (b) relationship specificity, and (c) emotional aspects of SIP.

The SIP model has been often used as a heuristic to explain the development of adversities in the peer group, such as aggression and rejection by other peers. For instance, several studies have shown that aggressive and rejected children are inclined to interpret intentions of others as hostile (e.g., Dodge, 1980; Dodge, Murphy, & Buchsbaum, 1984) and generate aggressive problem-solving strategies (Dorsch & Keane, 1994). Most of SIP is proposed to take place in an automatic fashion; that is, it cannot be inhibited. However, although Crick and Dodge (1994, p. 79) acknowledged the importance of incorporating "techniques for assessing automatic processes (using measures such as response time and assessment of priming effects)" to study social behaviors, research testing the SIP model has mainly relied on reflective measures and has thus not tested the automaticity assumption (Orobio de Castro, 2004; Orobio de Castro, Veerman, Koops, Bosch, & Monshouwer, 2002). Usually, hypothetical vignettes are presented to children, followed by questions assessing different SIP steps. Although some studies have aimed at differentiating automatic versus more reflective information processing by instructing children to respond immediately or after waiting for a while prior to giving the response (Orobio de Castro, Bosch, Veerman, & Koops, 2003; Rabiner, Lenhart, & Lochman, 1990), studies actually tapping online processing are practically nonexistent.

Second, the authors of the SIP model stressed the importance of considering social context when studying social cognitions (see Crick & Dodge, 1994). For instance, Feldman and Dodge (1987) found that differences between low- and high-status children with regard to SIP were evident only in a teasing situation,

providing support for the Person × Situation approach. However, with some exceptions, most of the earlier studies did not explicitly focus on studying contextual effects. More recent studies have demonstrated the role of the dyadic context in social-cognitive evaluations and behaviors (e.g., Card & Hodges, 2007; Hubbard, Dodge, Cillessen, Coie, & Schwartz, 2001; Ray & Cohen, 1997). For instance, Hubbard et al. (2001) showed that boys in mutually aggressive dyads attributed more hostility to each other than boys in randomly selected dyads. Burgess, Wojslawowicz, Rubin, Rose-Krasnor, and Booth-LaForce (2006) found that SIP was different in the friendship context as compared with other interaction partners. A conceivable explanation is that over time children have not only developed a general representation of their age-mates (Rudolph, Hammen, & Burge, 1995; Salmivalli, Ojanen, Haanpää, & Peets, 2005) but also representations specific to each peer and relationship.

The notion of relationship specificity is captured by mental structures called relational schemas, which "include images of self and others, along with a script for an expected pattern of interaction, derived through generalization from repeated similar interpersonal experiences" (Baldwin, 1992, p. 462). When children interact with different peers, peer-relational schemas are likely to be activated, influencing SIP. Moreover, not only social cognitions but also behaviors vary across different dyadic contexts. For instance, Card and Hodges (2007) demonstrated that although victimization occurs within friendship dyads, it is not as common as victimization in relationships characterized by mutual dislike (6.8% vs. 35%, respectively). Clear relationship effects on social cognitions can be found in middle childhood and adolescence: Social information is processed differently depending on the relationship partner (Peets, Hodges, Kikas, & Salmivalli, 2007). This supports the notion (Harter, Waters, & Whitesell, 1998) that the general view of peers develops during childhood and gets more fine-grained with age and experience. In contrast, younger children are not yet sensitive to different contexts. For instance, McDowell, Parke, and Spitzer (2002) found no context (i.e., whether they were with their mother, father, or a peer) effects on kindergarten children's goals and strategies.

Belongingness to the peer group also becomes increasingly important during middle childhood and early adolescence. Rejection by peers is associated with adjustment problems (for a review, see Parker & Asher, 1987), and it tends to be extremely stable (e.g., Coie, 1990), even when the child's behaviors change. The rejected status of a child is likely to be maintained through social-cognitive processes that are congruent with the affect felt toward him or her. For instance, the child's positive behavior might be attributed to unstable causes and negative behavior to stable dispositions (Hymel, 1986). Even if the original reasons for disliking the child (such as aggressiveness) do not exist any more, representations of the child and affect felt toward him or her by other peers might persist. It is likely that such affect-congruent social cognitions become automatized over the course of time and increase the likelihood of maintaining the rejected status of a child.

Third, although Crick and Dodge (1994) regarded emotions as an integral part of SIP, Lemerise and Arsenio (2000) integrated emotional processes into the SIP model more explicitly and thoroughly by suggesting that both experienced and perceived emotions influence interpretation of social information. This argument is supported by empirical findings. Negative emotional feelings induce or exacerbate attribution of hostility (Dodge & Somberg, 1987; Orobio de Castro, Slot, Bosch, Koops, & Veerman, 2003) and increase the likelihood of making more stereotypic judgments and relying on simple heuristic cues (Bodenhausen, Sheppard, & Kramer, 1994). Furthermore, others' emotional expressions influence SIP. For example, children attribute more hostile intent to angry provocateurs than to sad or happy provocateurs in hypothetical social situations (Lemerise, Gregory, & Fredstrom, 2005). Lemerise and Arsenio also suggested that the affective nature of the relationship with a peer (e.g., pleasure associated with a liked peer vs. anger associated with a hostile peer) influences SIP. For instance, children interpret the actions of their peers they personally like and dislike differently. Liked peers are perceived as less hostile than disliked peers (Peets, Hodges, & Salmivalli, 2008), and they are also held less responsible for their negative behaviors (Hymel, 1986). As relational schemas include cognitive as well as affective components (Baldwin, 1992), it could be expected that the activation of a particular relational schema triggers not only specific cognitions but also relationship-congruent affect. Moreover, when children have relationship histories with their peers, and especially when strong negative emotions are present (e.g., in the case of disliked peers), children tend to rely heavily on already established representations of these peers rather than on situational cues (e.g., Crick & Dodge, 1994). Given that emotional processes influence physiology and behavior automatically and rapidly (within hundreds of ms; Adolphs, 2002), it is surprising that experimental studies tapping relationship-specific affective processing in children and adolescents are nearly nonexistent.

Taken together, there is evidence that relationship-specific schemas of peers exist by early adolescence. There has been systematic interest in the role of such schemas in the processing of social information (e.g., Dodge & Rabiner, 2004), their automatic activation (Crick & Dodge, 1994), and their affective nature (Lemerise & Arsenio, 2000), but these phenomena have rarely been examined empirically. However, in the priming literature, automatic processing of affective and social information has been widely studied in adults. In typical affective priming experiments, participants' task is to categorize the affective valence (pleasant vs. unpleasant) of a probe stimulus preceded with a prime stimulus with congruent or incongruent valence. The valence of a probe stimulus is recognized faster if it is preceded by a prime stimulus of the same valence (for a review, see Klauer & Musch, 2003). The phenomenon has been demonstrated using a variety of primes, such as affective visual scenes (Hermans, De Houwer, & Eelen, 1994, Experiment 1) and facial expressions (Carroll & Young, 2005), and it is assumed to be highly automatic. Accordingly, we reasoned that a similar paradigm would be advantageous for studying automatic activation of adolescents' affective peer-relational schemas.

Three lines of evidence from studies with adults suggest that *facial identity primes* would activate affective, relationship-specific schemas in adolescents. First, influential models of face recognition (Bruce & Young, 1986; Haxby, Hoffman, & Gobbini, 2000) posit that when the face of a specific person is perceived, the person- and identity-related information is automatically retrieved from long-term memory to facilitate social interaction with the person. Second, functional brain imaging studies have shown that viewing faces of close friends and family members is associated with modulation of neural responses in areas which mediate episodic memory, representation of mental states of others, and emotional responses (Gobbini, Leibenluft, Santiago, & Haxby, 2004; Leibenluft, Gobbini, Harrison, & Haxby, 2004). As relational schemas consist of information about relationship-specific cognitions and emotions stored in long-term memory, the aforementioned data can also be interpreted as activation of relational schemas. Third, it has been argued that perception of names or faces of personally significant versus unimportant persons results in relationship-specific priming effects. In a study by Baldwin, Carrell, and Lopez (1990, Experiment 2), Catholic and non-Catholic students first read a sexual passage after which they were primed with an angry picture of either an unknown professor or the Pope and subsequently filled in a self-concept questionnaire. The Catholic participants who were primed with the Pope rated their self-concept as lower than those primed with the professor, thereby suggesting a relationship-specific priming effect. Similarly, Banse (1999) demonstrated that masked names and pictures of friends and romantic partners led to a more positive evaluation of subsequently presented Chinese ideographs. In a follow-up study, Banse (2001) showed that a brief presentation of the names and faces of the participants' relationship partner and Saddam Hussein (Experiment 1) or Charlie Chaplin and Hussein (Experiment 2) sped up the categorization of probe words with congruent (pleasant vs. unpleasant) affective valence. Importantly, the prime faces were intrinsically neutral as they all had neutral facial expressions. However, the participants had associated the intrinsically neutral faces of Chaplin and Hussein with pleasant and unpleasant affective reactions, respectively, via learning. Consequently, Banse (1999, 2001) argued that presentation of the pictures elicited respective affective reactions that produced the priming effects.

Taken together, there is evidence to suggest that the perception of a face of a familiar (liked or disliked) person with a neutral facial expression can elicit relationship-specific affective and cognitive changes—at least in adult participants. However, as participants of the aforementioned studies were probably not personally familiar with the persons depicted in the prime stimuli (i.e., the Pope, Hussein, or Chaplin), it can be questioned whether the stimuli used by Baldwin et al. (1990) and Banse (2001) actually primed *relational* schemas. It is indeed likely that none of the participants had ever personally met, for instance, Chaplin or Hussein, but still they would evaluate the picture of Chaplin as more pleasant. This raises the question whether such primes can be implemented to study relational schemas or whether they just tap the reputation-based knowledge of the prime stimuli.

The Current Study

In the current study, we employed the priming paradigm to assess whether adolescents' peer-relational schemas would be automatically activated when perceiving a familiar peer and whether there would be an effect on subsequent SIP. We selected pictures of children's peers to serve as primes for two reasons. First, peers can be considered highly salient figures for individuals during middle childhood and adolescence (e.g., Larson & Verma, 1999).

Second, unlike names, faces provide unambiguous and rapidly accessible information about identity (Haxby et al., 2000). We chose adolescents as our participants because previous studies have found that early adolescents discriminate between different relationship contexts (e.g., Peets et al., 2007; Peets et al., 2008), whereas younger children do not (McDowell et al., 2002). In addition, participants of the present study had interacted with most of their classmates for more than 5 years. Thus, they had spent enough time interacting with different peers to form relationship-specific representations of them.

Our study implemented four methodological advances over the previous research on relationship priming. First, to assure that participants were familiar with both "unpleasant" and "pleasant" primes, we used pictures (digital photographs) of participants' disliked and liked classmates as primes. Second, we wanted to ensure that we were actually priming *peer-relational* schemas. Therefore, instead of using primes that might be classified as pleasant or unpleasant by *all* participants (e.g., using the "most liked" and "most disliked" children as primes), we selected unpleasant and pleasant primes by means of individual nominations for disliking and liking. Third, by manipulating the prime display duration and prime – probe stimulus onset asynchrony (SOA), we aimed at determining whether the relationship-specific affective information is extracted from faces pre- or postattentively. Preattentive affective processing (e.g., Bargh, 1997) would involve priming effects with short (< 50 ms) masked presentation (Baldwin et al., 1990) that does not allow detailed semantic or perceptual identification of the stimulus, whereas postattentive processing (Storbeck, Robinson, & McCourt, 2006) would involve priming effects with longer stimulus presentations (> 150 ms) and SOAs (> 300 ms; Calvo & Nummenmaa, 2007; Hermans, De Houwer, & Eelen, 2001). In Experiments 1 and 2, we used happy (congruent with liked primes) and angry (congruent with disliked primes) facial expression probes. We chose angry facial expressions, instead of other negative expressions such as fear, to represent probes congruent with disliked primes as our previously collected, unpublished data indicate that children have greater expectations of anger toward disliked than liked or neutral peers. If an affective component of peer-relational schemas was automatically activated upon face perception, faster choice reaction times (RTs) for congruent (i.e., disliked peer/angry expression and liked peer/happy expression) than incongruent (i.e., disliked peer/happy expression and liked peer/angry expression) prime – probe pairs could be expected.

Fourth, we wanted to assess whether the affective priming effects would be also evident with regard to SIP. As a complementary methodological approach, pictures of participants' liked and disliked peers were presented as primes before hypothetical provocation and rebuff vignettes. The vignettes were followed by questions tapping three aspects of SIP: attributions of hostility, experience of anger, and likelihood of retaliation. As Peets et al. (2007) demonstrated that hostile attributions and behavioral strategies were highly relationship specific by using a reflective measure, we were interested in examining whether similar target-specific cognitions would be triggered automatically. On the basis of the assumption that liked and disliked primes activate respective relational schemas automatically, we expected that when displaying disliked peers as primes, adolescents would attribute more hostility, experience more anger, and would be more likely to retaliate toward a hypothetical peer.

Experiment 1

In Experiment 1, participants' task was to categorize facial expressions (angry/happy) of probe pictures. Before the probe displays, pictures of faces of participants' disliked and liked classmates were presented. Pictures of same-age peers whom participants did not know were used as neutral primes. This resulted in incongruent (disliked/happy and liked/angry), neutral (neutral/angry and neutral/happy), and congruent (disliked/angry and liked/happy) prime – probe pairs. To manipulate the information available for visual processing of the pictures and to test whether relational schemas are activated by preattentive processing of the primes, we used brief (50 ms) structurally masked (low visibility) or unmasked (high visibility) presentations (see Breitmeyer & Ogmen, 2000) of the primes and assessed both costs and benefits resulting from prime – probe pairs with congruent and incongruent affective valence.

Method

Participants

Twenty-four 6th-grade children (12 girls, mean age = 13 years) participated in the experiment. The participants were randomly selected from a larger sample of 238 children (109 girls, mean age = 13 years) who were involved in a longitudinal study on peer relations in Turku, a midsized town (175,000 inhabitants) in southwest Finland. As the Finnish population is ethnically and socioeconomically diverse rather homogeneous, information about family background was not asked. In Turku, the households with school-aged children consist of entrepreneurs (4.6%), people in upper white-collar positions (20%), lower white-collar positions (27.6%), blue-collar positions (32.3%), and others (16.9%). About 94% of people in the area are of Finnish origin. All the participating children received parental permission to take part in the experiments. We examined whether the participants in Experiment 1 differed from the rest of the subjects who did not participate in any of the three experiments ($N = 180$) on peer-nominated social (rejection) and behavioral (withdrawal, aggression) reputation scores. No significant differences were found ($t \leq 1.80$). In addition, 216 children (108 girls, mean age = 13 years) recruited from among the adolescents involved in the longitudinal study on peer relations posed for the stimulus photographs used in the three experiments. All participants were compensated with a movie ticket.

Apparatus and Stimuli

The stimuli were presented with a 1.2 Ghz Toshiba Portégé computer on a 12-in. screen. Presentation computer software (Neurobehavioral Systems) controlled stimulus presentation and response collection. Response accuracy and latency were collected through key presses with a Cedrus RB-834 response pad. The initial fixation marker was a white cross (diameter 1°). The prime pictures were black-and-white photographs representing the classmates whom participants had nominated as their liked and disliked peers or photographs of unknown same-age peers. Two pictures from each category were used for each participant. The probe stimuli consisted of 28 black-and-white photographs of angry (14) and happy (14) facial expressions posed by different actors (7 male and 7 female) selected from a well-known standardized stimulus set of facial expressions (Ekman & Friesen, 1976). Both the prime and the probe displays measured 7 × 16° of visual angle and were presented at the center of the screen. All stimuli were presented against a black background.

Procedure

Identifying peers used as primes. For each participant, liked and disliked peers were identified by means of a standard sociometric procedure (e.g., Coie, Dodge, & Coppotelli, 1982) approximately 1 month prior to the experiment. Participants were given a sheet with all the names of their same-sex classmates and were asked to nominate up to three same-sex peers they liked the most and the least. Self-nominations were not allowed. For each participant, two nominated disliked and two liked peers were chosen as primes. All the adolescents who were selected to participate in the experiments had nominated at least two peers they liked and two peers they disliked. If a participant had nominated three liked or disliked peers, we selected the two prime peers randomly. In addition, for each participant, pictures of two same-age, same-sex peers outside the adolescent's own school (from a different part of the town) were randomly selected to serve as neutral (unknown) primes.

Prime pictures. The prime pictures depicting children with neutral facial expressions were photographed approximately 1 month before the experiments. The photographs were taken at a distance of 1 m, and a special viewfinder was used to center children's nose tips at the center of the image. At least three photographs were taken of each child and four independent judges selected the photograph with the most neutral expression to be later used in the experiment. Finally, the selected photographs were converted to grayscale and cropped to include only the face area of the posers and to conform to the size (7 × 16°) of the probe pictures.

Controlling for the facial attractiveness of the primes. Studies have consistently demonstrated that children perceive attractive peers as more likable and less mean than unattractive peers (e.g., Dion, 1973; Langlois & Cookie, 1978). Thus, any potential priming effect in this study could also be attributed to facial attractiveness instead of relational schemas. To control for this possible confound, a separate sample of 55 adolescents (mean age 13 years, 29 girls) rated the facial attractiveness of the prime pictures used in the three experiments using a scale ranging from 1 (*unattractive*) to 5 (*attractive*). Ratings were conducted with paper-and-pencil questionnaires that contained 3 × 4 cm black-and-white prints of the prime faces presented in random order. Participants rated only same-sex faces. To ensure that participants did not rate any familiar faces, participants in the rating study were selected from different schools than the participants of the priming experiments. Additionally, participants were explicitly instructed not to rate the faces of children they thought they might know. Subsequently, a mean attractiveness rating was computed for each face. The mean attractiveness ratings for faces serving as disliked, unknown, and liked primes were subjected to a one-way independent samples analysis of variance (ANOVA). The main effect of prime type was not statistically significant, $F = 0.16$ (mean attractiveness rating across categories = 2.33), demonstrating that there were essentially no between-category differences in the facial attractiveness of the prime stimuli.

Experimental sessions and design. Participants were tested individually in a quiet room at their school with a transportable stimulus presentation and response-gathering system by the first author and a trained undergraduate research assistant. Before a testing session, participants were told that they would be presented a sequence of two pictures of faces on each trial. They were instructed to fixate at the center of the screen throughout the trials, ignore the first picture (the prime), and to concentrate on categorizing, as fast as possible, the facial expression of the second picture (the probe) as angry or happy. Before the experiment, participants were shown examples of angry and happy facial expressions and presented with 10 practice trials.

Figure 1a shows the sequence of events on each trial. A trial started with a presentation of the central fixation cross for 500 ms. Next, the prime picture (a disliked, neutral, or liked peer) was displayed for 50 ms, followed by a 50-ms display of a structural grayscale mask (low visibility) or a blank screen (high visibility), depending on the type of the trial. Finally, the picture depicting angry or happy facial expression was displayed until the participant pressed the response button. The response buttons (i.e., left vs. right button for angry vs. happy expressions) were counterbalanced across participants. Each participant performed two blocks of the task, each consisting of 28 trials of each type in random order totaling 168 trials per block and a grand total of 336 trials. A short break was held between the two blocks. After the experiment, participants were asked to nominate up to three peers they liked and disliked the most in order to control for the stability of the relationship schemas (i.e., liking vs. disliking) and asked whether they knew the adolescents serving as neutral (unknown) primes. The experimental conditions were thus combined into 2 (visibility: low vs. high) × 3 (prime–probe congruency: incongruent vs. neutral vs. congruent) fully within-subjects design.

Results

To verify the stability of the relationship schemas, we assessed the congruency of peer nominations collected 1 month before and immediately after the experiment by examining whether children nominated the same targets among their liked and disliked peers. On average, the stability was high (79%). We

also compared whether nominations for liking versus disliking were equally stable by repeated measures t tests and found that the stability was slightly higher for liking (88%) than for disliking (70%) peers, $t(23) = 2.10, p < .05$. On average, participants made 6% errors (i.e., categorized the probe picture wrongly) in the expression categorization task. RT data from correct responses were collapsed across the blocks. Anticipations (RTs < 80 ms), and retardations (RTs 2.5 *SD* above individual mean) were excluded from the data analysis according to the suggestions by Ratcliff (1993). These accounted for 4% of the trials. Next, participant-wise mean RTs were calculated for each Visibility × Prime–Probe Congruency condition. These data with pooled 95% confidence intervals (see Masson & Loftus, 2003) are presented in Figure 2. The mean RTs were subjected to a 2 (visibility: low vs. high) × 3 (prime–probe congruency: incongruent vs. neutral vs. congruent) repeated measures ANOVA. The results demonstrated a main effect of visibility, $F(1, 24) = 7.30, p < .05, \eta_p^2 = .23$, and prime–probe congruency, $F(1, 24) = 3.24, p < .05, \eta_p^2 = .12$. Moreover, the Visibility × Prime–Probe Congruency interaction proved significant, $F(2, 24) = 3.13, p < .05, \eta_p^2 = .12$. RTs were faster in the low visibility condition (834 vs. 840 ms, respectively). Additionally, planned comparisons (corrected for multiple comparisons) revealed that for the high-visibility condition, both incongruent, $F(1, 24) = 6.21, p < .05, \eta_p^2 = .21$, and congruent, $F(1, 24) = 9.00, p < .05, \eta_p^2 = .27$, probes were categorized more slowly than neutral probes. However, none of the comparisons reached significance ($F < 1$) in the low-visibility condition. Also, to control for potential gender moderation effects, we repeated the ANOVAs in this and all subsequent experiments with gender as a between-groups factor and verified that gender did not interact with the priming effects in any of the experiments.

Discussion

In line with previous research using affective pictorial primes and probes (Hermans, Spruyt, De Houwer, & Eelen, 2003, Experiment 1), no affective priming effect was found for the low-visibility condition. In contrast, the data for the high-visibility condition suggest that the relational schemas might have been activated by the primes. However, the results did not show the traditional affective priming effect. Instead, longer RTs were demonstrated after congruent as well as incongruent prime–probe pairs (i.e., after emotional primes) as compared to the probes preceded by neutral primes. This somewhat surprising finding becomes understandable if we consider the processing stream of face perception in more detail. The widely accepted models of face recognition (Bruce & Young, 1986; Haxby et al., 2000) assume that structural encoding of faces, which is necessary for identity recognition is undertaken prior to the retrieval of knowledge related to that person. The emotional reactions potentially arising from the stimulus faces in the current experiment were contingent on the recognition of the *identity* of the face: Across the different prime categories, the stimuli had equally neutral expressions and were rated as equally attractive; thus, they could be considered as *intrinsically neutral* stimuli. However, each participant saw faces of peers that they considered as pleasant and unpleasant due to their relationship history with the persons depicted in the stimuli. Consequently, it is likely that both the facial identity recognition and the *subsequent* retrieval of the affective information (i.e., relational schemas) attached to the perceived individual could not be undertaken during the short 100-ms period between the prime and the probe stimulus demanding response. This argument is supported by the fact that facial identity priming is usually demonstrated at much longer SOAs (up to 700 ms; see Bruce & Valentine, 1986) than affective priming (around 300 ms; see Hermans et al., 2001). In the current experiment, it is likely the participants were able to *detect* the liked and disliked primes as familiar (i.e., either pleasant or unpleasant) but could not undertake the more elaborate *discrimination* of the stimulus identity as liked or disliked. Subsequently, both liked and disliked primes resulted in interference and led to slower responses in both congruent and incongruent priming conditions as compared to the neutral priming condition. This is also in line with the model of postattentional affective processing by Storbeck et al. (2006), which suggests that the features of any object must first be integrated, and the object itself identified prior to affective analysis. In other words, postattentional affective priming would first involve the facial identity recognition, which would subsequently be followed by the affective analysis of the target face.

Experiment 2

If the affective priming effect is contingent on the recognition of the facial identity, it could be expected that affective priming would be manifested if the duration of the prime display was longer. We conducted Experiment 2 to test this hypothesis. We increased the prime display duration to 150 ms and replaced the stimulus visibility manipulation with a SOA (300 vs. 450 ms) manipulation. The selection of the SOAs was based on the SOAs used in the facial identity priming paradigms (Bruce & Valentine, 1986) as well as recent findings with the affective priming paradigm that have demonstrated that, though affective priming is automatic, affective processing is postattentive (Calvo & Nummenmaa, 2007). If the priming effect would only be contingent on the resources available for the visual processing of the prime, we expected that priming effects would be manifested at both SOAs. However, if the priming would be contingent on facial identity recognition and subsequent activation of affective relational schemas, priming effects were expected to emerge only at the 450-ms SOA.

Method

Participants

Thirty 6th-grade adolescents (10 girls, mean age = 13 years) not participating in Experiment 1 served as participants subjects and were compensated with a movie ticket. All the participants were randomly chosen from the same participant pool as those in Experiment 1. Of the 31 adolescents originally participating in the study, one had to be removed from the data analysis due to a chance-level performance (56% correct) in the expression recognition task. With regard to measures of rejection, withdrawal, and aggression, there were no differences between the children who participated in Experiment 2 and those who did not participate in any of the three experiments ($N = 180$, $t \leq 1.26$).

Apparatus, Stimuli, Experimental Design, and Procedure

Apparatus, stimuli, experimental design, and procedure were similar to those in Experiment 1, with three exceptions. First, the prime display duration was increased to 150 ms. Second, instead of the structural mask, a blank screen was presented after the primes on all trials. Third, two different prime–probe SOAs (300 vs. 450 ms) were used (see Figure 1b for events in trials). This resulted in a 2 (SOA: 300 vs. 450 ms) × 3 (prime–probe congruency: incongruent vs. neutral vs. congruent) fully within-subjects design.

Results

Again, the average stability of the affect felt toward the peers was high (73%), and it was slightly higher for liked (81%) than for disliked (65%) peers, $t(29) = 2.40$, $p < .05$. There were no differences in the facial attractiveness of the disliked, unknown, and liked prime stimuli, $F = 1.40$. The mean attractiveness rating across categories was 2.32. Mean RTs (an average of 7% errors and 2.5% of anticipations and retardations omitted) for the different SOA × Prime–Probe congruencies are presented in Figure 3. The mean RTs were analyzed with a 2 (SOA: 300 vs. 450 ms) × 3 (prime–probe congruency: incongruent vs. neutral vs. congruent) repeated measures ANOVA. The main effect for SOA reached significance, $F(1,29) = 40.55$, $p < .05$, $\eta_p^2 = .58$, demonstrating the classic foreperiod effect (see Niemi & Näätänen, 1981). RTs were faster for 450-ms than for 300-ms SOAs (794 vs. 833 ms, respectively). Although the main effect of

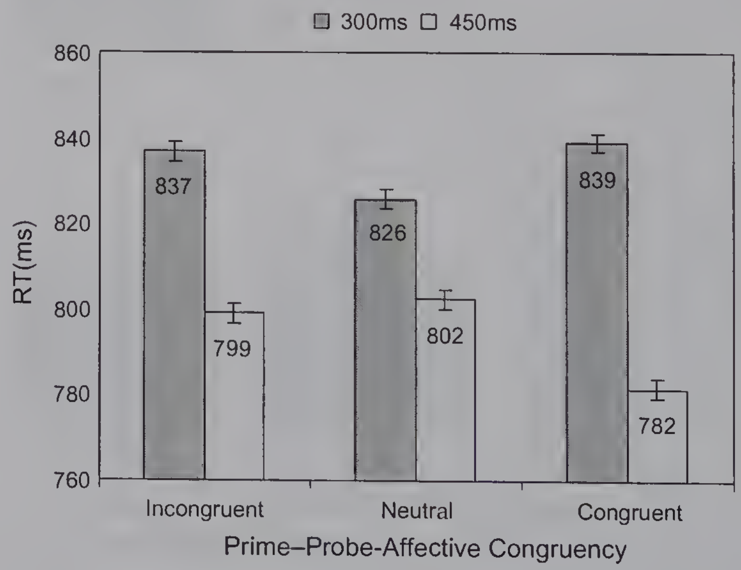

Figure 3. Mean response latencies (ms) with pooled 95% confidence intervals as a function of stimulus onset asynchrony and prime–probe affective congruency in Experiment 2.

prime – probe congruency did not reach significance, $F = 1.26$, the SOA × Prime – Probe Congruency interaction was significant, $F(2, 58) = 3.85, p < .05, \eta_p^2 = .12$. Multiple comparisons revealed that this interaction resulted from the fact that at the 450-ms SOA, congruent probes were categorized faster than neutral, $F(1, 29) = 6.57, p < .05, \eta_p^2 = .19$, and incongruent, $F(1, 29) = 4.75, p < .05, \eta_p^2 = .30$, probes (RTs = 781, 802, and 798 ms, respectively). However, neutral probes were not categorized faster than the incongruent probes, $F < 1$. There were no differences in RTs between congruent, neutral, and incongruent probes at the 300 ms SOA, $F < 1$.

As the congruency variable was pooled across liked and disliked primes, we also wanted to analyze whether the liked and disliked primes would produce equally strong priming effects. For that purpose, we compared the priming scores for happy (i.e., $\mathrm{RT}_{\text{disliked – happy}} - \mathrm{RT}_{\text{liked – happy}}$) and angry ($\mathrm{RT}_{\text{liked-angry}} - \mathrm{RT}_{\text{disliked – angry}}$) facial expressions with each other on the 450-ms SOA condition. Both priming scores were positive (22 vs. 12.50 ms) showing that disliked primes facilitated recognition of angry expressions and liked primes facilitated recognition of happy expressions, but there was no statistically significant difference between the priming scores for happy versus angry expressions, $t < 1$. This suggests that disliked and liked primes speeded up the categorization of congruent facial expressions to an equal extent.

Discussion

The main finding of Experiment 2 was that an affective priming effect was demonstrated when the prime – probe SOA was 450 ms. RTs were faster for congruent (disliked / angry or liked / happy) than for neutral or incongruent prime – probe pairs. This implies that the affective component of relational schemas is activated automatically—albeit not very rapidly—upon perception of a familiar peer. The results suggest that the activation of peer-relational affective information resulting from face perception is contingent on postattentional recognition of facial identity. The SOA manipulation revealed that the priming effect was crucially dependent on the total processing time and not the prime display time. Namely, the prime display time was similar (150 ms) for both SOAs, but the affective priming effect only emerged when the prime – probe SOA was 450 ms. Accordingly, presenting a face for 150 ms was definitely enough for identity recognition, but the affective priming effect took approximately 450 ms to occur. The time course of the observed priming effect was longer than what is typically observed in affective priming studies. The maximal affective priming effects are usually observed at 150 – 300 ms SOAs (see Hermans et al., 2001), although recently Carroll and Young (2005) demonstrated affective priming effects for facial expressions at SOAs of 250 and 750 ms. However, facial identity priming effects are typically manifested at 700-ms SOA (Bruce & Valentine, 1986). As the occurrence of the priming effects in the current studies would require recognition of the facial identity of the depicted person, it is understandable that the time course of the observed priming effect resembles that of facial identity priming.

Experiment 3

Experiments 1 and 2 relied on priming facial expression recognition with faces of participants' peers. Although Experiment 2 demonstrated that relationship-specific affective reactions can be automatically elicited by a brief presentation of liked and disliked peers' faces, it remains open whether activation of relational schemas would influence other aspects of online SIP, such as interpretation of ambiguous situational cues, feelings of anger, or likelihood of retaliation. As outlined in the Introduction, SIP is usually studied by using hypothetical vignettes and asking questions which tap different steps of SIP. It has, however, been questioned (Orobio de Castro, 2004) whether such measures capture the automaticity of SIP.

To test the automaticity assumption, Experiment 3 implemented a computerized hypothetical vignette task with a priming manipulation. According to Crick and Dodge (1994), the way children handle peer provocation and rebuff situations is especially critical for their social adjustment in the peer group. Participants were thus presented, on the computer screen, with short vignettes (two or three sentences) describing either provocation or rebuff by a hypothetical anonymous same-sex protagonist. The protagonist's behavior had always a negative consequence for the participant, but the intent of the protagonist was displayed as ambiguous. The vignettes were followed by questions measuring attributions of hostility, experience of anger, and willingness to retaliate. Based on two assumptions—(a) relational schemas are activated automatically and (b) relational schemas affect the way adolescents process social information about the particular peer—we expected that after perceiving the disliked primes, participants would attribute more hostility, experience more anger, and be more likely to retaliate against the protagonist in the vignette.

Method

Participants

Thirty 6th-grade adolescents (10 girls, mean age = 13 years) participated in the experiment. The participants were randomly chosen from the same participant pool used in Experiments 1 and 2. All the participating children had parental permission to take part in the experiments. Again, no significant difference was found between the participants and the rest of the sample who did not participate in any of the three experiments ($N = 180$) on peer-nominated rejection, withdrawal, and aggression scores ($t \leq 0.97$).

Apparatus and Stimuli

Apparatus and prime stimuli were similar to those used in Experiments 1 and 2. Vignettes were presented on the computer screen, with 1 vignette occupying the screen at a time. Altogether 24 vignettes were used describing social interactions in which the participant was provoked (12 vignettes; e.g., "Pretend that you are playing soccer with other boys/girls. You turn away from the other players for a while, and suddenly somebody kicks the ball to your back. It hurts very much") or rebuffed (12 vignettes, e.g., "Pretend that you are in your classroom and you hear two boys/girls talking about a bike trip taking place next weekend. You would also like to join them. You go over and ask them if you could go to the trip as well. One of the boys/girls says 'No!'") by a hypothetical same-sex peer (protagonist).

Each vignette was followed by three questions that appeared on the screen one at a time: (a) Did the protagonist intend to harm you? (*attribution of hostility*; b) Would you be angry at him/her? (*experience of anger*) and (c) Would you do something to get even? (*retaliation*). A white response scale line measuring 16° of visual angle was presented below each question and horizontally centered on the screen. Verbal labels for the extreme values (*not at all* vs. definitely) of the response scale were presented at the corresponding ends of the response scale. Otherwise, the scale range was arbitrary to the participants. In terms of response recording, the scale actually ranged from −250 (*not at all*) to +250 (*definitely*). A red vertical line served as a cursor for answering the questions. It measured 3°, was centered vertically on the response scale, and could be moved along the response scale with the mouse. All stimuli were presented against a black background.

Procedure and Design

To identify the peers used as primes, we followed the same procedure as in Experiments 1 and 2. Testing was conducted at schools similarly to the previous experiments. Participants were told that the study concerned decision making in various social situations. They were told that they were going to see a series of short texts describing social interactions with peers, followed by questions about their own reactions to the situations. They were also informed that they would see some pictures of faces during the experiment, but it was stressed that the pictures were completely irrelevant to the actual experiment. Participants were instructed to fixate at the center of the screen at the beginning of the trials, ignore the picture of the face, and to read the subsequent vignette carefully and respond to the questions using the mouse. Figure 4 shows the sequence of events for each trial. A trial started with a presentation of the central fixation cross for 500 ms. Next, the prime picture (disliked, neutral, or liked peer) was displayed for 150 ms, followed by a 300-ms display of a blank screen, resulting in a SOA of 450 ms. Next, a vignette was presented on the screen until the participant double-clicked the mouse button, indicating that he or she had finished reading the vignette. After each vignette, the questions regarding attribution of hostility, experience of anger, and likelihood of retaliation were presented in a random order. Each question was presented on a separate display, and participants responded using the mouse to move the line cursor along the response scale. Before the experiment, participants were presented with four practice trials, followed by a single experimental block consisting of four trials of each type (Prime Type × Vignette Type) in random order totaling 24 trials, with the same three questions asked after each trial. The experimental factors were combined to a 3 (prime type: disliked vs. neutral vs. liked) × 2 (vignette type: provocation vs. rebuff) × 3 (question type: attribution of hostility vs. experience of anger vs. retaliation) fully within-subjects design.

Results

The average stability of the affect felt toward the peers was high (75%), and it was slightly higher for liked (79%) than for disliked (71%) peers, $t(29) = 2.50$, $p < .05$. The mean attractiveness rating for prime faces was 2.44, and there were no between-category differences in the perceived attractiveness of the disliked, neutral, and liked primes, $F = 0.5$. Subject-wise mean response scores (see Table 1) were computed for each condition in the vignette task. The scores were subjected to a 3 (prime type: disliked vs. neutral vs. liked) × 2 (vignette type: provocation vs. rebuff) × 3 (question type: attribution of hostility vs.

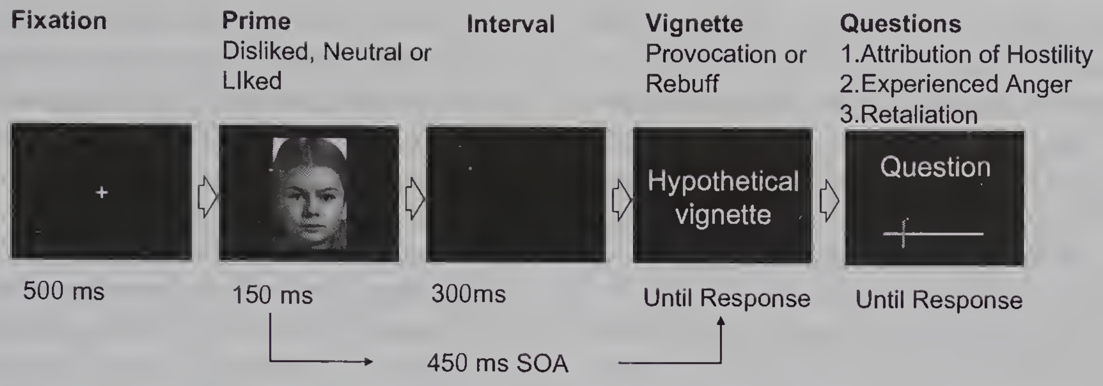

Figure 4. Sequence of events on a trial in Experiment 3.
Note. SOA = stimulus onset asynchrony.

experience of anger vs. retaliation) repeated measures ANOVA. This yielded significant main effects of prime type, $F(2, 58) = 3.38$, $p < .05$, $\eta_p^2 = .12$, and vignette type, $F(1, 29) = 4.02$, $p < .05$, $\eta_p^2 = .12$, as well as a Vignette Type × Question Type interaction, $F(2, 58) = 9.14$, $p < .05$, $\eta_p^2 = .24$. Multiple comparisons for the prime type showed that when compared to disliked, $F(1, 29) = 4.84$, $p < .05$, $\eta_p^2 = .14$, and neutral, $F(1, 29) = 4.54$, $p < .05$, $\eta_p^2 = .14$, primes, the liked primes resulted in less attributions of hostility, experience of anger, and retaliative responses. However, differences between disliked and neutral primes were nonsignificant, $F < 1$.

Planned comparisons for the Vignette Type × Question Type interaction demonstrated that for provocation vignettes, mean experience of anger was higher than attributions of hostility, $F(1, 29) = 10.74$, $p < .05$, $\eta_p^2 = .27$, and retaliation, $F(1, 29) = 37.99$, $p < .05$, $\eta_p^2 = .57$, and that mean attributions of hostility were higher than mean retaliation, $F(1, 29) = 4.84$, $p < .05$, $\eta_p^2 = .14$. For the rebuff vignettes, mean attributions of hostility were higher than experience of anger, $F(1, 29) = 5.23$, $p < .05$, $\eta_p^2 = .15$, and retaliation, $F(1, 29) = 44.84$, $p < .05$, $\eta_p^2 = .61$. Moreover, mean experience of anger was higher than mean retaliation, $F(1, 29) = 39.83$, $p < .05$, $\eta_p^2 = .58$. In addition, it was found that when compared to rebuff vignettes, provocation vignettes resulted in greater experience of anger, $F(1, 29) = 12.99$, $p < .05$, $\eta_p^2 = .31$, and retaliation, $F(1, 29) = 4.20$, $p < .05$, $\eta_p^2 = .13$, but no differences were found for attributions of hostility, $F < 1$.

Discussion

The results of Experiment 3 demonstrated that the automatic activation of relational schemas also had an effect on how adolescents processed social information other than facial expressions (cf. Experiment 2). In the case of disliked and neutral primes, participants attributed more hostility to the hypothetical peer, experienced more anger, and were more willing to retaliate as compared to liked primes. The results showed that nonretaliation was more common than retaliation across different priming conditions, suggesting that getting back at someone (even toward the disliked peer) might be infrequent. Still, we should be cautious when making such a claim as we did not have behavioral measures to assess retaliation (i.e.,

Table 1
Means and Standard Errors of Responses as a Function Prime Type, Vignette Type, and Question Type

	Disliked		Neutral		Liked	
	M	*SE*	*M*	*SE*	*M*	*SE*
Provocation vignettes						
Attributions of hostility	−4.43	17.13	−9.73	17.93	−11.90	15.87
Experience of anger	28.53	16.69	29.94	17.05	2.15	14.92
Retaliation	−62.19	17.73	−46.27	20.17	−71.62	15.65
Rebuff vignettes						
Attributions of hostility	−2.09	13.73	−3.51	14.71	−8.10	15.46

Retaliation	−71.08	16.73	−71.51	15.87	−95.87	13.32

Note. Ratings were provided on a scale that ranged from −250 (*not at all*) to +250 (*definitely*).

whether the participants actually retaliated against the peer) and associations between SIP steps and social behaviors are not necessarily very strong (for reviews, see Orobio de Castro et al., 2002; Yoon, Hughes, Gaur, & Thompson, 1999). Also, stronger retaliatory responses might have emerged if the sample had consisted of highly rejected or aggressive adolescents.

Overall, Experiment 3 corroborates our previous findings that relational schemas are automatically activated upon perception of a familiar peer. Additionally, as participants showed greater experience of anger for trials primed with disliked versus liked peers, the results provide additional support for our argument (Experiment 2) that perceiving a face of a familiar peer exerts an influence on subsequently arising affective reactions. Moreover, these findings also elaborate the results obtained in Experiment 2 in two ways. First, they show that the relationship-specific priming effects are not restricted to the affective domain but that activation of relationship schemas also influences interpretation of situational cues (intentionality) as well as response decision (likelihood of retaliation), which are two of the core components of the SIP model (Crick & Dodge, 1994). Second, the data suggest that the priming effects are relatively long lasting. Whereas a single trial in Experiments 1 and 2 lasted for less than 1 s, the average trial duration in Experiment 3 was 17.5 s. This underlines the importance of relationship schemas in guiding social behavior—although the schemas can be activated rapidly (in around 450 ms) they influence the social behavior at least for tens of seconds. It must, however, be noted that as the delay between the prime and the response was much longer in Experiment 3 than in Experiments 1 and 2, it is likely that participants had engaged in more reflective processing (see Orobio de Castro, 2004) in Experiment 3 when responding. Nevertheless, we argue that the priming effects have interacted with this reflective processing in automatic fashion, as the primes were presented only briefly and were irrelevant to the vignette task.

General Discussion

We conducted three experiments to study automatic relationship-specific SIP. In Experiments 1 and 2, we primed angry versus happy facial expression recognition with the facial identity of liked, neutral, and disliked peers to examine whether the affective component of peer-relational schemas would be automatically activated. In Experiment 3, we presented similar identity primes before hypothetical provocation and rebuff vignettes in order to investigate whether automatic activation of peer-relational schemas would influence SIP. The affective priming effect found in Experiment 2 showed that when the prime and probe stimuli were congruent in terms of their affective valence, the categorization of facial expressions was faster when the stimulus display duration and prime–probe SOA were long (150 and 450 ms, respectively). In case of the short display duration (50 ms), presentation of both liked and disliked peers as primes slowed the categorization of the subsequent facial expression when the primes were masked with a blank screen. When structural masking was applied, no priming effects were manifested. Together Experiments 1 and 2 demonstrate that relationship-specific affective reactions are activated by the mere perception of a familiar face, if sufficient time is given between the presentation of the facial identity and the demanded response. This suggests that children do hold different views of different peers and that different affective reactions are associated with different individuals.

In addition, Experiment 3 demonstrated that automatically activated relationship-specific schemas influenced social-cognitive evaluations of hypothetical peers. More specifically, when the disliked peer served as a prime, participants attributed more hostility to the protagonist in the vignette, experienced more anger, and were more likely to retaliate. These findings have important implications for the (a) automaticity, (b) relationship specificity, and (c) emotional aspects of SIP. We will next address these issues in more detail.

Automaticity of SIP

An important question is whether the peer-relational schemas were activated automatically in the current experiments. Traditionally, automatic processes are assumed to be (a) fast and efficient (b) unintentional, and (c) unconscious (for review, see Moors & De Houwer, 2006). At the short display duration (Experiment 1), disliked and liked but not neutral primes resulted in interference only when masked with a blank screen. At first, this might seem to contradict the first assumption of automatic processing. However, this finding probably reflects latency due to the hierarchy of face recognition processes, that is, the fact that identity recognition precedes affective evaluation as discussed above. For the priming effects to occur, facial identity encoding must be undertaken prior to retrieving the peer-related affective associations from the long-term memory. Although this process can take up to 450 ms to accomplish, it might still be undertaken in automatic fashion. This argument is corroborated by the fact that the data seem to fulfill other criteria for automatic processing. First, the priming effects were unintentional in the sense that they occurred even though the prime faces were task irrelevant, and participants were instructed to ignore the prime face and concentrate on categorizing the facial expression of the probes or reading the vignettes and responding the subsequent questions. Second, automatic versus conscious (or volitional) priming results in different patterns of RTs. Posner and Snyder (1975) have demonstrated that automatic aspects of priming will produce facilitation for related targets with no inhibition for unrelated targets, whereas conscious anticipatory effects will produce facilitation for related *and* inhibition for unrelated targets. As the 450-ms SOA condition of Experiment 2 demonstrated facilitation without inhibition ($\mathrm{RT}_{\mathrm{congruent}} < \mathrm{RT}_{\mathrm{neutral}} = \mathrm{RT}_{\mathrm{incongruent}}$), we consider the priming effect to result from the automatic activation of the peer-relational schemas.

So far, although SIP in children and adolescents has been assumed to be highly automatic (Crick & Dodge, 1994), and priming has been often mentioned as a necessary method to study online SIP (e.g., Burks, Laird, Dodge, Pettit, & Bates, 1999; Crick & Dodge, 1994), empirical research on the issue is almost nonexistent. Thus, considering that our existing knowledge about SIP originates mainly from the studies using reflective measures (e.g., questions presented after vignettes), the present study adds valuable information by providing direct evidence for the automatic retrieval of relationship-specific information.

Relationship Specificity of SIP

In line with other recent studies showing relationship specificity in SIP (Burgess et al., 2006; Peets et al., 2007; Peets et al., 2008), our results suggest that adolescents have different representations of peers that, once activated, affect subsequent information processing. Although SIP patterns were initially regarded as trait-like characteristics (Crick & Dodge, 1994), there is growing evidence that information processing is much less rigid and is influenced by the target peer's reputation and the relationship between the child and the target peer (Dodge, 1980; Hymel, 1986; Peets et al., 2007). In addition, relationship information has been described as being organized in a hierarchical way (e.g., Bretherton, 1990), with children having a general working model of peers, or general peer beliefs (Rabiner, Keane, & McKinnon-Lewis, 1993; Rudolph et al., 1995; Salmivalli et al., 2005), as well as more specific relational schemas, or knowledge structures containing information specific to different peers and relationships with them. When children first meet an unfamiliar peer, they tend to rely on their general peer beliefs developed from past experiences within family and among peers. However, these beliefs can change as a result of the interactions children have with those peers (Rabiner et al., 1993). Thus, although some children and adolescents tend to have a generalized view of others as hostile, it does not necessarily mean that they could not have a positive experience with some peers and develop a positive view of those peers.

Affective Components of Relational Schemas

The results of the present study show that the affective nature of the relationship (i.e., liking vs. disliking a peer) is an important aspect of peer-relational schemas and thus support the notion by Lemerise and Arsenio (2000) that emotional information associated with different peers influences SIP. Specifically, the data suggest that the emotions associated with certain disliked or liked peers are prone to be activated automatically in social situations and will promote affect-congruent cognitions and, subsequently, behaviors. Given that emotions occur rapidly and involuntarily, we argue that these affect-congruent modulations in social cognitions and behavior are crucial for maintaining already-established relationships. It should be pointed out that although the representation of a disliked peer might also capture emotions such as disgust, fear, and sadness, anger was chosen as a probe most congruent with the negative prime in the present study. It is indeed likely that adolescents dislike some peers because they are *afraid* of them rather than feel anger toward them. In addition, as reasons for dislike become more heterogeneous with age (see Hayes, Gershman, & Halteman, 1996), anger might not be the core emotion felt toward the disliked peer. Whether the same effect would be obtained by using probes with different facial expressions should be empirically tested. This would enable more fine-grained analysis of the organization of the affective peer-relational schemas. In addition, our results suggest that the sociometric nomination procedure used widely in the research on peer relations is a valid method to be used to differentiate between the peers whom children have positive and negative representations of. As aggression is one of the main reasons during middle childhood and early adolescence why someone is disliked, it could be argued that differences between liked and disliked peers might be just a function of their general behavioral reputation. However, studies have shown that even when the aggressiveness of the target peers has been taken into account, affective nature of the relationship has still an effect on social-cognitive processes (Peets et al., 2007).

Moreover, research using reflective measures has shown that preadolescents' evaluations of different peers are congruent with their affect felt toward those peers (Peets et al., 2008). For example, in the case of disliked peers, they make more hostile attributions, expect less relational and instrumental outcomes for aggression, and have higher self-efficacy beliefs for aggression, with the opposite being true for liked peers. Experiment 3 further demonstrated that affect-congruent social-cognitive evaluations are automatic. We should point out, however, that we did not find different priming effects for disliked versus unknown peers. This was not totally unexpected. Studies in adults have demonstrated that unfamiliar individuals with prototypical neutral facial expressions are evaluated as mildly unpleasant instead of neutral (Lee, Kang, Park, Kim, & An, 2007). Accordingly, such unpleasantness of the neutral faces of strangers probably explains why the disliked and neutral primes result in similar effects in Experiments 2 and 3. In addition, it has been shown that general beliefs about unfamiliar peers are not associated with beliefs about familiar peers (Rabiner et al., 1993), suggesting that actual experiences within the peer group can shape children's initial beliefs. Thus, future research could test whether negative attitudes toward unknown peers become more negative or positive over time as a result of children's interactions with these peers. Moreover, as our results imply that adolescents might, in general, have more hostile than prosocial beliefs of strangers, future priming studies manipulating the facial expression (happy vs. neutral vs. angry) of the liked, neutral, and disliked peer primes should be conducted to assess how situational factors can modulate the effect of these beliefs on SIP.

Online SIP is assumed to affect which behavioral response is enacted in a given situation (the "sixth step" in the SIP model). Consequently, the practical significance of the current results is that the automatic activation of relationship-specific information could automatically trigger certain behavioral patterns concordant with this information. Experiment 3 showed that although there were differences between disliked and liked primes with regard to retaliation, adolescents were more likely to be nonretaliative than retaliative toward the hypothetical peer across different priming conditions. It is in accordance with a study by Peets et al. (2008), who also demonstrated that although it was common for preadolescents to hold different social-cognitive evaluations of their liked and disliked peers, self-reported aggression even toward disliked peers was rather infrequent. Thus, whether social cognitions translate into aggressive behavior might be dependent on the characteristics of the individual and/or the interaction partner. For instance, it may be that only aggressive individuals act on their aggression-encouraging cognitions toward the peers who are physically weak and rejected by other peers. It is possible that if we had studied, for instance, extremely aggressive children, their responses would have been more retaliatory than nonretaliatory in nature.

Our results confirm that affect is a core component of relationships: Children are inclined to be negatively biased toward their enemies and positively biased toward their friends (Parker & Gamm, 2003; Peets et al., 2007). However, one should note that in our experiments, the relationship primes were chosen on the basis of *unilateral* nominations. Mutual friendships and antipathies are relationships that have much more personal meaning and relevance to children than relationships characterized by unilateral positive or negative affect. It is thus likely that the magnitude of the priming effects would have been larger if we had selected targets characterized by mutual disliking or liking. Previous studies (e.g., Card & Hodges, 2007) have indeed shown that children are more likely to be recipients of aggression by mutual antipathies than by friends or peers characterized by unilateral dislike and that mutual dislike serves as a context in which negative experiences have the most detrimental effect on children's adjustment.

Although aggression is, to a great extent, relationship specific, there are individuals who have tendencies to be more aggressive across relationships (Coie et al., 1999; Peets et al., 2008). Future studies could examine whether automatic processing is different, for instance, for aggressive versus nonaggressive individuals. It is possible that due to their aversive experiences in the peer group, especially rejected-aggressive children and adolescents have hostility schemas, which are activated in the case of unknown peers. Over time, SIP might become less affected by situational cues and more influenced by the activation of already existing (relationship-specific) representations of peers. Burks et al. (1999, p. 803) have suggested that "the more ambiguous the environmental information, the more the individual has to rely on the chronically accessible construct, and, thus, the resulting representation is composed predominantly of information from the knowledge base." Consequently, automatic processes might serve as key factors explaining stability of the peer reputation and its resistance to change. For instance, when a child dislikes someone, he or she is prone to process the information about this peer so that it would be congruent with the negative affect felt toward the peer. When other members of the group (i.e., classmates) share this negative view, social-cognitive processes consistent with the representation might be even less likely to change. For instance, a study by Hymel (1986) demonstrated that negative behaviors by disliked peers were attributed to more stable causes than negative behaviors by liked peers. Thus, although the behavior of a rejected child could be modified, other peers might still interpret the new behavior in light of existing representations and respective social-cognitive processes. It could be expected that differentiated social-cognitive evaluations are even more stable when the classroom structure remains the same over time (which is often the case in Finnish schools).

Participants of our experiments were early adolescents. Although reasons for liking and disliking someone become more abstract and diverse when children get older (see Hayes et al., 1996), affect-congruent social cognitions are also present in older adolescents (see Hymel, 1986). Previous studies that had failed to find such effects among young children (e.g., McDowell et al., 2002) have utilized the traditional, reflective measures. Priming studies would provide an alternative way to examine whether relationship-specific schemas of peers start to emerge already early on but cannot yet be reflected upon.

Finally, our findings offer one possible explanation why relationship effects have been found to account for just as much of the variance in children's dyadic aggression as actor or target effects (Coie et al., 1999). Namely, our study suggests that the affective person-related information is also activated automatically upon perceiving a familiar individual and that the activated information guides both affective and SIP. Future research could examine whether there are also individual differences in terms of how automated this processing is. Although in the current study we used an affective priming technique, we would expect priming effects to be evident regardless of the specific priming method. Taken together, the current findings thus encourage further research on the relationship specificity and automaticity of social behaviors and on the mechanisms explaining it.

Romantic Partner Selection and Socialization During Early Adolescence

University of North Carolina at Chapel Hill

This prospective study examined romantic partner selection and socialization among a sample of 78 young adolescents (6th–8th graders). Independent assessments of adolescent and romantic partner adjustment were collected before and after relationships initiated via peer nomination and self-report. Prior to their relationship, adolescents and partners were significantly alike on popularity, physical attraction, and depressive symptoms. Controlling for initial similarity, partners' popularity, depressive symptoms, relational aggression, and relational victimization significantly predicted changes in adolescents' functioning in these areas over time. However, the magnitude and direction of change varied according to adolescents' and partners' prerelationship functioning. In general, adolescents who dated high-functioning partners changed more than those who dated low-functioning partners, and partner characteristics predicted greater change among low- versus high-functioning adolescents. Results were consistent even when controlling for best friend characteristics. The current findings are among the first to demonstrate unique contributions of romantic partner characteristics to adolescents' psychosocial functioning.

The emergence of romantic relationships is among the most significant psychosocial developments of adolescence. Romantic experiences appear to be associated with a diverse range of psychosocial outcomes. Some studies document enhancements in social status, romantic self-concept, self-esteem, and feelings of belonging, whereas others link romantic involvement to higher levels of depression, mood swings, conflict, and antisocial behavior (for reviews, see Collins, 2003; Furman & Shaffer, 2003). The processes by which romantic relationships could affect adolescent adjustment are not well understood. Characteristics of romantic partners are believed to be an important factor but little is known about adolescents' choice of romantic partners or the consequences of romantic partner characteristics on psychosocial functioning (Collins, 2003). The current study addresses this important gap in the literature by examining partner selection and socialization in adolescents' romantic relationships.

At all ages, partner selection and socialization processes appear to promote homophily between relationship partners (McPherson, Smith-Lovin, & Cook, 2001). A general tendency to be attracted to similar others increases the odds of choosing partners who share commonalities. Once the relationship is formed, partners tend to shape and reinforce similarities over time. Among youth, homophily has been documented in friendships and peer groups (Espelage, Holt, & Henkel, 2003; Hogue & Steinberg, 1995). In adulthood, homophily has been reported among dating, cohabitating, and married couples (Blackwell & Lichter, 2004; McPherson et al., 2001).

To the extent that homophily pervades social relationships, we might also expect to find homophily within adolescents' romantic relationships. If true, adolescents and partners would be similar to one another prior to relationship formation (selection) and become more similar over time (socialization). Yet we know of no published studies on this topic. Findings of adult romantic homophily are suggestive; however, there are likely to be developmental differences in the partner characteristics that are salient to adolescent and adult relationships. Research on peer influence offers insights about which partner characteristics could be salient during adolescence, yet

friend, peer group, and romantic relationships have distinctive features (e.g., sexuality) and are thus not inherently redundant. Studies of adolescents' romantic partner preferences are informative regarding the characteristics adolescents find appealing (e.g., Hansen, 1977; Regan & Joshi, 2003), but preferences do not necessarily predict adolescents' actual choices or behavior. Understanding how adolescents select romantic partners and the contributions of romantic partner characteristics to adolescents' psychosocial functioning would provide important information about individual differences in links between romantic involvement and adjustment. In the current study, we assessed prerelationship similarities among prospective romantic partners and examined whether romantic partners' prerelationship characteristics predicted adolescents' subsequent psychosocial functioning.

Romantic Partner Selection

Studies of interpersonal attraction and adult romantic homophily have consistently identified status dimensions as important to partner selection (McPherson et al., 2001; Regan & Joshi, 2003). Status dimensions include sociodemographic factors (e.g., age, ethnicity) as well as ascribed characteristics, such as social standing or physical attractiveness. The current study focused on two ascribed status variables that are salient to young adolescents—physical appearance and popularity. Adolescents rate appearance as important to romantic partner selection, and adult partners' self-ratings of attractiveness tend to be positively related (Feingold, 1988; Regan & Joshi, 2003; Roscoe, Diana, & Brooks, 1987). Accordingly, we predicted that adolescents would select romantic partners who are similar to themselves in physical attractiveness and body appeal. Just as friends tend to be similar in social status, we expected that adolescents would also select partners who shared similar levels of popularity (Haselager, Hartup, van Lieshout, & Riksen-Walraven, 1998).

The function and structure of young adolescents' peer groups could further promote similarity between romantic partners. Because friendships and romantic relationships serve comparable functions, adolescents could use similar criteria to select friends and romantic partners (Furman, Brown, & Feiring, 1999). In addition, early romantic relationships are initiated within mixed-sex peer groups (Connolly, Craig, Goldberg, & Pepler, 2004), which are themselves subject to homophily effects at both the friend and the peer-group level (Espelage et al., 2003; Hogue & Steinberg, 1995). Hence, similarity could be particularly evident during early adolescence, when adolescents and partners are more likely to both belong to peer groups that already share similar features. Friends could also encourage romantic partner similarity through their roles as judges and brokers of romantic relationships. By defining what makes for suitable partners, friends could actively discourage the selection of partners who are discrepant in developmentally salient social or behavioral norms, such as social status or aggression (Brown, 1999). Such counsel could be especially prescriptive for young adolescents who are nearing peak susceptibility to peer conformity (Berndt, 1979; Krosnick & Judd, 1982; Steinberg & Silverberg, 1986).

For these reasons, we expected that adolescents would be similar to their romantic partners on dimensions that are important to friendships and peer groups at this age, including popularity, physical appearance, depressive symptoms, peer aggression, and peer victimization (Espelage et al., 2003; Kandel, Davies, & Baydar, 1990; Mariano & Harton, 2005; Prinstein, 2007; Stevens & Prinstein, 2005). However, similarity at the time of partner selection could be greater for observed than for psychological characteristics. After all, overt similarities are more easily identified than internal psychological characteristics during the initial attraction phase of relationships (Kandel, 1978; Urberg, Degirmencioglu, & Tolson, 1998). Accordingly, we predicted that prospective partners would be more similar in their physical appearance, peer popularity, peer aggression, and peer victimization than in their levels of depressive symptoms.

Implicit in these hypotheses is the suggestion that friends and romantic partners are alike. If adolescents select friends who are similar to themselves and romantic partners serve similar functions as friends, we would expect adolescents to choose romantic partners who are similar to their friends. Accordingly, we predicted that friends' and romantic partners' levels of popularity, physical appearance, peer aggression, and peer victimization would be significantly correlated. The salience of physical appearance to romantic attraction led us to anticipate that adolescents would be more similar to prospective romantic partners than friends on this particular dimension.

Romantic Partner Socialization

Adolescents may select peers to whom they are similar, but over time, these peers may also influence adolescents' behavior. For instance, friend characteristics predict changes in adolescents' depressive symptoms, peer aggression, and peer victimization over time, even after controlling for similarity (Espelage et al., 2003; Hogue & Steinberg, 1995; Jaccard, Blanton, & Dodge, 2005). In the current study, we examine whether romantic partner characteristics are predictive of similar changes in adolescents' psychosocial functioning. Such direct evidence of romantic partner socialization is currently absent from the literature. However, research by Adams and colleagues indicates that young adolescents rate romantic partners to be at least as influential as friends on their thoughts, feelings, and behavior (Adams, Laursen, & Wilder, 2001). These findings, coupled with the time and emotion adolescents invest in romantic relationships, suggest that partners could be important socializing agents.

Researchers typically estimate peer socialization by assessing whether peers' functioning at one time significantly predicts youths' functioning at a later time. The current study employed a similar design. We assessed whether partners' psychosocial functioning prior to the relationship predicted change in adolescents' psychosocial functioning after the two began dating. Changes in adolescents' psychosocial functioning predicted by partners' prerelationship functioning are interpreted as evidence of partner socialization.

We expected that some partner characteristics would be important to selection or socialization, whereas others would be important to both. As noted earlier, appearance and popularity should each be important to partner selection. Yet only partners' popularity was expected to exert a significant socialization effect when predicting adolescents' functioning over time. To the extent that status grading is an important aspect of early romantic relationships, partners' prerelationship popularity should be positively associated with adolescents' subsequent popularity (Skipper & Nass, 1966). Prior findings of significant peer socialization effects on adolescents' depressive symptoms, peer aggression, and peer victimization suggested that romantic partners' functioning in these areas could also be important predictors. Furthermore, we expected that some partner characteristics would predict adolescents' subsequent functioning even in the absence of initial partner similarity. For instance, covert characteristics, such as internalizing symptoms, could be less important to partner selection but then gain influence as partners spend time together (Baker, Milich, & Manolis, 1996; Stevens & Prinstein, 2005).

In the majority of homophily studies, peer socialization is examined in an additive model where peer characteristics are tested as main effects under the assumption that all peers influence all adolescents in a roughly equivalent manner. More recently, Hartup (1999, 2005) has argued that peer socialization is best conceived as an interaction between characteristics of the socializing agent and the socialized individual. In other words, some partners could be more influential than others, and some adolescents could be more open to influence than others. Relatively few studies have examined peer influence from this perspective; however, those that have suggested that healthy and negative peer influences are contingent on both partners' initial level of functioning (e.g., Adams, Bukowski, & Bagwell, 2005; Dishion & Owen, 2002).

Similarly, we hypothesized that high- and low-functioning romantic partners might predict different patterns of change for high- and low-functioning adolescents. For example, dating a partner with few psychosocial problems (i.e., high functioning) could be especially helpful for adolescents experiencing more psychosocial problems (i.e., low functioning) but could be less useful for adolescents with few problems. In support of this idea, having a friend who is low on aggression predicts decreases in adolescents' aggression over time, but only for adolescents who are initially more aggressive (Adams et al., 2005). In the current study, we expected that adolescents with more prerelationship problems who dated high-functioning partners would show improvements in psychosocial functioning over time. Adolescents with few prerelationship problems who paired with similarly high-functioning partners were not expected to change.

In contrast, the characteristics of low-functioning partners (i.e., those with more prerelationship problems) were not expected to predict much change in adolescents' psychosocial functioning. High-functioning adolescents, who have few psychosocial problems, could be resistant to the problems of their low-functioning partners (Adams et al., 2005; Dishion & Dodge, 2005). On the other hand, low-functioning partners could reinforce the problems of low-functioning adolescents once the two begin dating (Duncan, Boisjoly, Kremer, Levy, & Eccles, 2005; Poulin, Dishion, & Burraston, 2001). In either case, we expected to see little change among adolescents dating low-functioning partners.

The Current Study

Although romantic partners are presumed to affect adolescents' development, we know little about how adolescents select romantic partners or the consequences of their choices. This could be partly due to methodological challenges, as isolating selection from socialization effects to predict change as a function of partner characteristics requires longitudinal designs that can identify individuals' future romantic partners. In the current study, we identified adolescent couples within a longitudinal school-based sample. Using a follow-back design, we traced adolescents and romantic partners to a prior data collection to examine prerelationship similarities. This allowed for a relatively pure estimation of selection effects, as neither adolescents nor partners identified themselves as being romantically involved at that time. Socialization effects of romantic partners were then estimated by using partners' prerelationship characteristics to predict changes in adolescents' psychosocial functioning over the time prior to (Time 1) and after relationships were established (Time 2).

Young adolescents' friend and romantic relationships are frequently developed at school, and our school-based design allowed us to examine emerging romantic relationships in their broader social context. Although the data points are necessarily anchored around the initiation of romantic relationships, estimates of friendship similarity prior to the initiation of romantic relationships provide important information about the role of friends in romantic partner selection and socialization. Comparing the characteristics of adolescents' extant friends to those of prospective romantic partners as well as comparing the degree of similarity within friend and romantic dyads would offer new data on the relative importance of general and relationship-specific peer selection criteria in early adolescence. The inclusion of best friends also permitted us to examine romantic partner socialization while accounting for co-occurring socialization by best friends. We expected to find similarity but not redundancy across the two relationships. Romantic relationships are a unique facet of adolescent social development (see Collins, 2003; Furman & Shaffer, 2003, for reviews). Adolescents themselves report different expectations for friend and romantic relationships (Connolly & Goldberg, 1999), and empirical associations between the two relationships are significant but modest (Furman, Simon, Shaffer, & Bouchey, 2002).

Method

Participants

Participants included 78 adolescents (48% female) who were in the sixth (32 %), seventh (35%), and eighth (33%) grades at the beginning of the study. The ethnic composition of the sample included 87% European American, 2% African American, 4% Asian American, 2% Latino American, and 6% from mixed-ethnic backgrounds. Participants were enrolled in public schooling within a town of fairly homogenous middle-class socioeconomic status (per capita income = $32,301). According to school records, 11% of children were eligible for free/reduced lunch. These participants were part of a larger study (*n* = 520) designed to examine developmental trajectories of depressive symptomatology. All sixth-through eighth-grade students were invited to participate in the first phase of data collection for the larger study (Time 1). Consent forms were returned for 92% of families (*n* = 784); of these, 80% of parents gave consent for their child's participation (*n* = 637, 74% of total population). Students who were absent on one of the testing days (*n* = 10), provided incomplete data (*n* = 15), or refused to assent (*n* = 4) were excluded from analyses, yielding a final sample of 598 participants at Time 1. A total of 520 (87%) of these participants were available for testing 11 months later at Time 2, when students were in Grades 7 through 9. Attrition was due to participants moving away from the area (*n* = 36), absenteeism (*n* = 7), incomplete data (*n* = 30), and refusal to participate (*n* = 5). No significant difference was found between adolescents who participated in two versus one time points.

The current sample included adolescents who indicated on the Networks of Relationship Inventory (Furman & Buhrmester, 1985) that they began a romantic relationship between Time 1 and Time 2. Specifically, participants were asked whether they had a boyfriend or girlfriend, the name of this person, and how long this person had been their boyfriend or girlfriend. On average, these romantic relationships lasted 13.63 weeks (*SD* = 19.10). Because romantic partner and best friend data were needed to examine selection and socialization effects, only those adolescents whose best friend and romantic partner were also participants in the study were included in our sample. To avoid dependency in the data, one member of any reciprocally nominated romantic dyad was randomly dropped from the sample. This resulted in a data set in which each adolescent served as only a target participant or as a romantic partner. Similarly, no adolescent appeared as both a friend and a romantic partner in the data set. We did not drop any target adolescent who was named as another target adolescent's best friend because friendships were not the focus of the study and doing so could have resulted in a biased sample of adolescents whose best friends were not dating.

The 78 target participants were compared to 62 participants who reported a romantic relationship at Time 2 but who did not meet other study criteria (i.e., the best friend or romantic partner did not also participate in the study). No significant group differences emerged for gender, grade, or any Time 1 primary study variables. Similar analyses were conducted to compare adolescents in the larger sample who were and were not dating. Compared to nondating adolescents, students in romantic relationships were seen by peers as more physically attractive, $t(518) = 6.93$, $p < .001$, $M = 0.55$, $SD = 1.29$ versus $M = -0.10$, $SD = 0.89$; more popular, $t(518) = 6.68, p < .001, M = 0.53, SD = 0.98$ versus $M = -0.10$, $SD = 0.95$; less sad, $t(518) = -4.78, p < .001, M = -0.27$, $SD = 0.46$ versus $M = 0.06$, $SD = 1.08$; and less physically victimized by peers, $t(518) = -2.36$, $p < .05$, $M = -0.19$, $SD = 0.77$ versus $M = 0.04$, $SD = 1.06$.

Procedure

A letter introducing the study was mailed to the homes of all potential participants, and a consent form was sent home with each student. Parents were asked to either grant or deny their consent for their child's participation, and adolescents were asked to return the consent form regardless of their parent's decision. At both time points, questionnaires were administered to adolescents in their classrooms over 2 days. Each participant received a small token of appreciation (e.g., a key chain), a $5 gift certificate, and a raffle entry for a Sony Playstation 2 or Microsoft Xbox.

Measures

Popularity. Sociometric peer nominations were used to obtain measures of adolescents' peer perceived popularity at both time points. Students at this school were organized into teams about twice the size of traditional academic classrooms. Using an alphabetized roster of all classmates within their academic team, participants were asked to select an unlimited number of peers who were "most popular." The order of names was counterbalanced on these rosters (e.g., Z through A) to control for possible effects of alphabetization on nominee selection. A continuous measure of perceived popularity was computed by standardizing the number of most popular votes with higher scores indicating greater popularity (Rose, Swenson, & Waller, 2004).

Physical appearance. The peer nomination procedure described earlier also was used at both time points to obtain peer ratings of physical attractiveness and body appeal. The question for physical attractiveness was "Who is good looking?" and the question for body appeal was "Who is physically fit?" As described earlier, the number of nominations that each participant received for each question was summed and standardized relative to their teammates.

Peer-rated sadness. Peer nomination procedures were used to assess participants' sadness at each time point from the question "Who looks sad and unhappy most of the time?" The number of nominations received by each participant was summed and standardized relative to their teammates.

Self-rated depressive symptoms. The Children's Depression Inventory (CDI) was used to obtain self-reports of depressive symptoms at both time points (Kovacs, 1992). The CDI contains 27 items that assesses affective, cognitive, motivational, and somatic symptoms of depression. For each item, youth choose one of the three statements, scored 0 through 2, that best describe their level of depressive symptoms over the prior 2 weeks. Mean scores were computed for each student, with higher scores reflecting greater levels of depressive symptoms. In the current sample, Cronbach's alphas were .87 at Time 1 and .86 at Time 2.

Peer-rated aggression. Peer nomination procedures were used to assess participants' relational and physical aggression from the questions "Who ignores others or spreads rumors about others when they are mad at them?" (relational) and "Who starts fights, says mean things, and picks on others?" (physical). The number of nominations received by each participant for each item was summed and standardized relative to their teammates.

Peer-rated victimization. Peer nomination procedures were used to assess participants' relational and physical victimization from the questions "Who has lies, rumors, or mean things said about them?" (relational) and "Who gets picked on or teased by other kids?" (physical). The number of nominations received by each participant for each item was summed and standardized relative to their teammates.

Results

Preliminary Analyses

Ratings of depressive symptoms were obtained from adolescents as well as peers, and the two were significantly related ($r = .43$, $p < .001$). Prior to data analysis, scores for self-reported depressive symptoms were standardized to be consistent with sociometric measures and allow for meaningful comparisons across domains of functioning. Means and standard deviations for all measures are presented in Table 1 for target adolescents, romantic partners, and best friends. No significant mean differences were found between target adolescents', romantic partners', and best friends' corresponding values across any of these domains.

Partner Selection

Our first goal was to estimate romantic partner selection effects by examining prerelationship similarities in developmentally salient domains. Intraclass correlations between adolescents' and romantic partners' scores on each Time 1 variable indicated significant prerelationship similarities in four domains: popularity, body appeal, physical attractiveness, and self-rated depressive symptoms (see Table 2). To test the hypothesis that similarity would be greater for more observable characteristics, Fisher's r-to-z tests were calculated to compare the magnitude of similarity correlations across domains (Cohen, 1988). Among the four significant correlations, adolescent to romantic partner similarities were significantly larger for popularity than for physical attractiveness ($p < .001$) and self-rated depressive symptoms ($p < .05$). In addition, the similarity correlation for each of the four significant domains was significantly larger than each similarity correlation where no significant correlation was found (i.e., peer-rated sadness, physical aggression, relational aggression, physical victimization, and relational victimization; all $ps < .01$).

Parallels between adolescents' friend and romantic relationships had led us to hypothesize that these two relationship partners would share similar characteristics. The intraclass correlations between adolescents and their best friends on Time 1 variables paralleled those reported above for adolescents and prospective romantic partners, with the notable exception of body appeal (see Table 2). Specifically, adolescents were similar to both their best friend and romantic partner on popularity, attractiveness, and self-rated depressive symptoms. In addition, adolescents and best friends were significantly alike on Time 1 relational aggression. Comparing the magnitude of the similarity correlations across relationships revealed that adolescents were significantly more like friends than romantic partners on popularity, Williams's $t(75) = -2.65$, $p < .01$, and significantly more like romantic partners than friends on body appeal, Williams's $t(75) = 2.85$, $p < .01$. No significant differences in adolescents' similarity to romantic partners versus best friends were found for any of the other Time 1 variables. To further explore links between adolescents' friends and romantic partners, we computed Pearson correlations between the Time 1 characteristics of the two relationship partners (see Table 2). Adolescents' extant best friends and prospective romantic partners were significantly similar in their popularity, body appeal, attractiveness, and self-rated depressive symptoms at Time 1.

Partner Socialization

The second goal of this study was to estimate romantic partner socialization effects by testing whether partners' prerelationship characteristics predicted change in adolescents' functioning over time. We predicted that romantic partner characteristics would significantly predict adolescents' functioning at Time 2, even after accounting for co-occurring

Table 1
Means and Standard Deviations for All Primary Time 1 Variables

	Target adolescents		Best friends		Romantic partners	
Time 1 variables	Standardized	Unstandardized	Standardized	Unstandardized	Standardized	Unstandardized
Popularity	.38 (1.13)		.29 (1.19)		.58 (1.30)	
Body appeal	.37 (1.01)		.77 (2.95)		.60 (1.10)

socialization by best friends. However, we expected that the strength and direction of the effects would vary according to both partners' and adolescents' prerelationship functioning.

Data analytic strategy. To test these hypotheses, we conducted a series of regression analyses to test the main and interactive effects of adolescents' and romantic partners' prerelationship characteristics on adolescents' psychosocial functioning at Time 2 (Baron & Kenny, 1986; Holmbeck, 2002). Prior to the analyses, all predictors were centered to reduce multicollinearity (Aiken & West, 1991). For each Time 2 outcome, adolescents' corresponding Time 1 scores were entered in Step 1 to assess stability over time. Best friends' Time 1 scores were entered in the second step to control for co-occurring socialization by friends. Romantic partners' Time 1 scores were entered in a third step to assess the main effect of romantic partner characteristics. The product term of adolescents' and romantic partners' Time 1 scores was entered in the final step to assess whether adolescents' and romantic partner's Time 1 functioning interacted to predict adolescents' Time 2 functioning.

All significant Adolescent × Partner interactions were subsequently probed following procedures described by Holmbeck (2002) in which slope estimates are calculated and examined at high ($M + 1\ SD$) and low ($M - 1\ SD$) levels of the moderator (Aiken & West, 1991). Significant interactions were probed twice, once with romantic partners' prerelationship functioning as the moderator and a second time with adolescents' prerelationship functioning as the moderator. This strategy allowed us to determine how change in adolescents' functioning over time varied according to partners' prerelationship functioning and by adolescents' prerelationship functioning. The two are related, though not identical, ways of decomposing and understanding the observed moderator effects.

Examining the moderating effects of romantic partner characteristics identifies whether change in adolescents' psychosocial functioning is greater when partners are high versus low functioning. Specifically, post hoc analyses assess the association between adolescents' functioning at Time 1 and Time 2 (i.e., stability) when partners are high and low functioning. Thus, change (i.e., lack of stability) in adolescents' characteristics over time as a function of romantic partners' characteristics is indicated by a nonsignificant slope (i.e., unstandardized beta). Examining the moderating effects of adolescents' prerelationship characteristics identifies whether romantic partner characteristics predict different amounts or types of change for high- versus low-functioning adolescents. Specifically, the post hoc analyses assess the association between partners' functioning at Time 1 and adolescents' functioning at Time 2 when adolescents were initially high versus low functioning. For these analyses, significant effects as a function of adolescents' initial functioning are indicated by a significant slope.

Controlling for co-occurring socialization by adolescents' best friends in Step 2 of the analyses provided a conservative test of romantic partner socialization. To the extent that friend and partner effects are confounded, this strategy could underestimate romantic partner socialization. To examine this possibility, we reran the regressions described above without controlling for best friend characteristics (i.e., eliminating Step 2 in the regressions). The pattern of results was very similar to that obtained when controlling for best friend characteristics, with almost identical beta weights and ΔR^2 values. No additional significant direct effects emerged for romantic partners' Time 1 characteristics. The similarity of results across the two sets of analyses suggested that romantic partner predictors were not redundant with friend predictors. Therefore, the results presented below are those from the analyses that include best friend values as a covariate in Step 2.

Popularity. Romanic partners' Time 1 popularity was not directly associated with adolescents' Time 2 popularity. However, as hypothesized, the interaction between adolescents' and partners' Time 1 popularity was a significant predictor (see Table 3). Results from post hoc probing of the moderating effects of romantic partners' popularity are plotted in Figure 1, where the lines depict the association between adolescents' popularity at Time 1 and Time 2 when partners' Time 1 popularity was high versus low. The beta coefficients were significant whether adolescents dated either high- or low-popular partners ($b = .75$, $p < .001$ and $b = 1.08$, $p < .001$, respectively), suggesting little change in adolescents' popularity over time. However, the beta coefficient was smaller for adolescents who dated high-popular partners, suggesting that these adolescents experienced more change in popularity than those who dated low-popular partners.

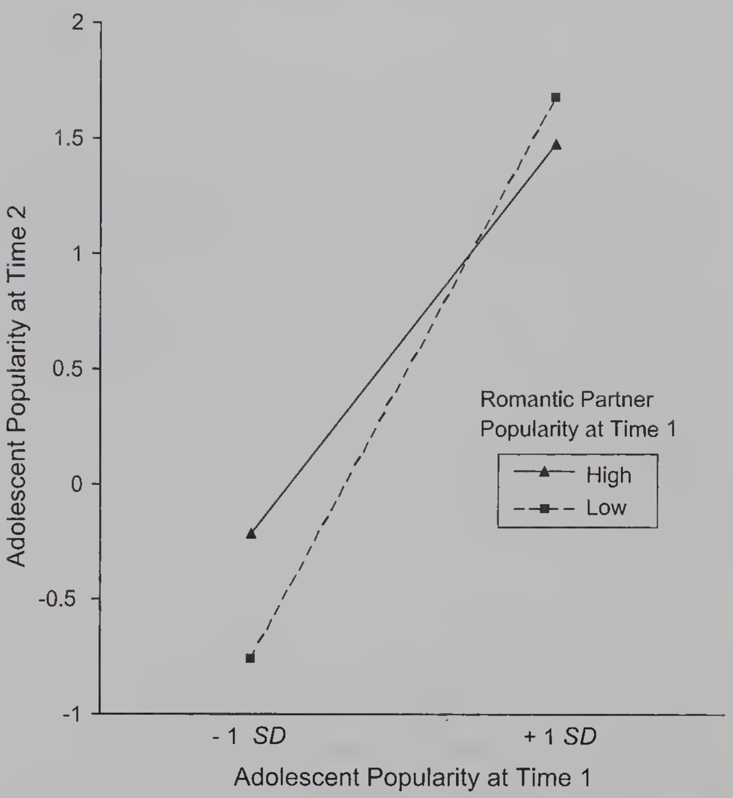

Figure 1. Graph of simple slopes for interactions between adolescent and romantic partner Time 1 popularity in predicting adolescents' Time 2 popularity with romantic partners' popularity as the moderator.

Results from post hoc probing of the moderating effects of adolescents' prerelationship popularity are plotted in Figure 2, where the lines depict the association between partners' popularity at Time 1 and adolescents' popularity at Time 2 when adolescents' Time 1 popularity was high versus low. Here, it can be seen that romantic partners' initial popularity predicted the subsequent popularity of low- but not high-popular adolescents ($b = .15$, $p < .05$ and $b = -.05$, $p = ns$, respectively). Among adolescents who were initially low in popularity, those who dated a high-popular partner were more popular at Time 2 than those who dated a low-popular partner.

Considered together, these two sets of post hoc analyses facilitate a better understanding of how the combination of adolescents' and partners' initial popularity predict change in adolescents' popularity over time. Figure 3 illustrates these patterns of change for low- and high-popular adolescents when they dated

Table 3

Summary of Hierarchical Regression Analyses Examining Main and Moderating Effects of Romantic Partner Characteristics on Adolescents' Popularity, Body Appeal, and Physical Attractiveness at Time 2

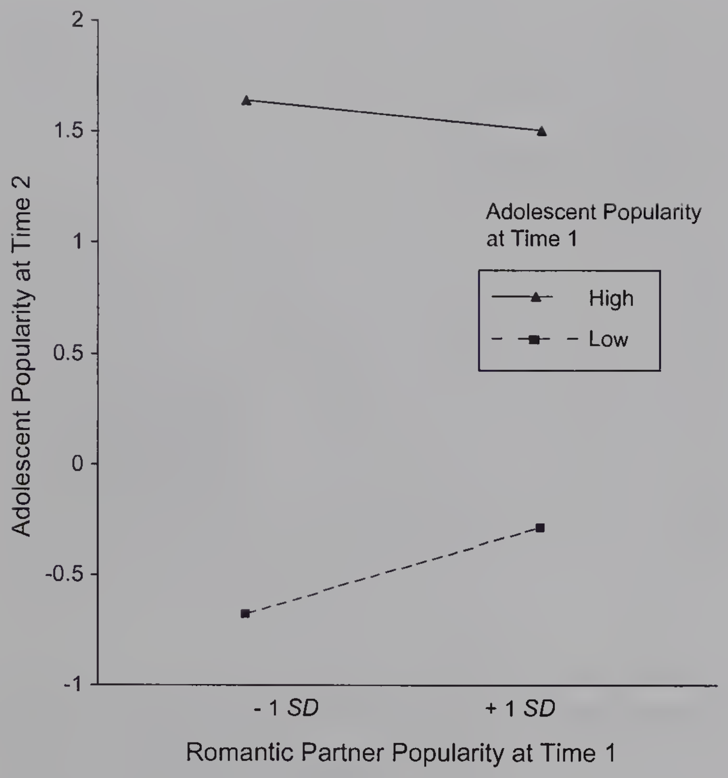

Figure 2. Graph of simple slopes for interactions between adolescent and romantic partner Time 1 popularity in predicting adolescents' Time 2 popularity with adolescents' popularity as the moderator.

low- versus high-popular partners. High and low functioning are defined in relation to the sample mean ($M \pm 1$ SD). Adolescents who were highly popular at Time 1 remained fairly stable over time, regardless of their partners' popularity. In contrast, low-popular adolescents changed, but this was limited to those who dated high-popular partners. Low-popular adolescents who dated a high-popular partner became more popular, whereas low-popular adolescents who dated a low-popular partner did not change.

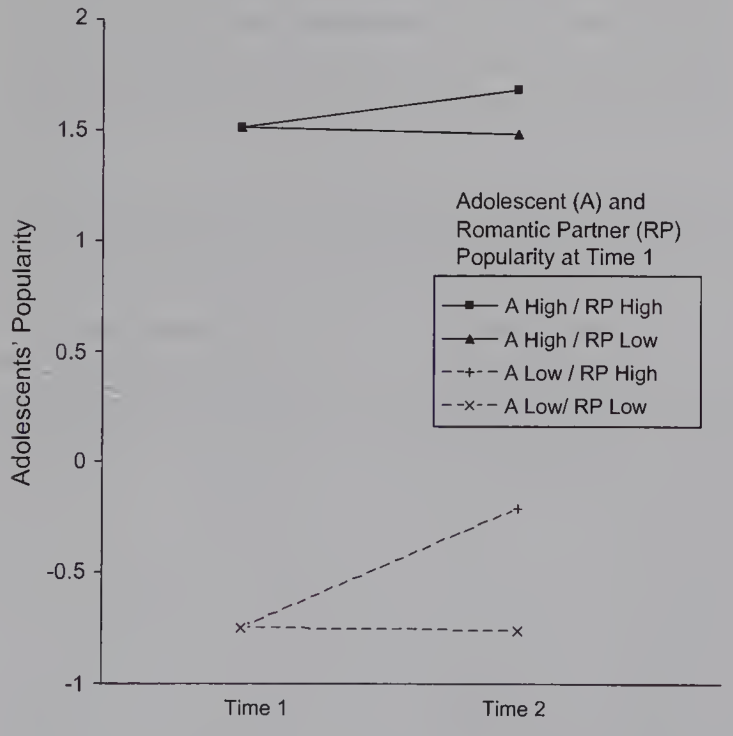

Figure 3. Graph of change patterns in adolescents' popularity from Time 1 to Time 2 by combination of adolescent and partner popularity levels at Time 1.

Physical appearance. Consistent with our hypotheses, romantic partners' physical appearance (i.e., body appeal or physical attractiveness) did not exert a significant main effect on adolescents' peer-rated appearance, nor were there interactive effects between romantic partners' and adolescents' physical appearance in predicting Time 2 ratings of physical appearance (see Table 3).

Depressive symptoms. Romantic partners' peer-rated sadness at Time 1 was not directly associated with adolescents' Time 2 peer-rated sadness. As hypothesized, however, the interaction between adolescents' and partners' Time 1 sadness was a significant predictor (see Table 4). Results from post hoc probing of the moderating effects of adolescents' romantic partners are illustrated in Figure 4, and the results are illustrative of partner-moderated effects for other "problem-oriented" outcomes reported subsequently. Figure 4 plots the association between adolescents' Time 1 and Time 2 sadness when romantic partners' Time 1 sadness was high versus low. Adolescents' Time 1 sadness predicted their Time 2 sadness when partners' initial sadness was high ($b = 1.06$, $p < .001$) but not low ($b = -.10$, *ns*). These findings suggest that adolescents who dated partners who were initially low on sadness changed more than those who dated partners who were initially high on sadness.

Results from post hoc probing of the moderating effects of adolescents' initial sadness are illustrated in Figure 5, and the findings are illustrative of adolescent-moderated effects for subsequently reported "problem-oriented" outcomes. Here, the association between partners' sadness at Time 1 and adolescents' sadness at Time 2 is plotted when adolescents' initial sadness was high versus low. Romantic partners' Time 1 sadness predicted adolescents' Time 2 sadness, but only for adolescents who were initially high on peer-rated sadness, $b = .84$, $p < .01$ for high sad and $b = -.11$, *ns* for low sad. Among adolescents who were initially high on sadness, those who dated a partner low on sadness were less sad at Time 2 than those who dated a partner high on sadness.

Considered together, the two sets of post hoc analyses facilitate a better understanding of how the combination of adolescents' and partners' initial sadness predict change in adolescents' sadness over time. Figure 6 illustrates these patterns of change for low- and high-functioning adolescents when

they dated low- versus high-functioning partners. It is also illustrative of the results for self-reported depressive symptoms, relational aggression, and relational victimization. High and low functioning are defined in relation to the sample mean ($M \pm 1$ *SD*). High-functioning adolescents (i.e., low on sadness, depressive symptoms, aggression, victimization)

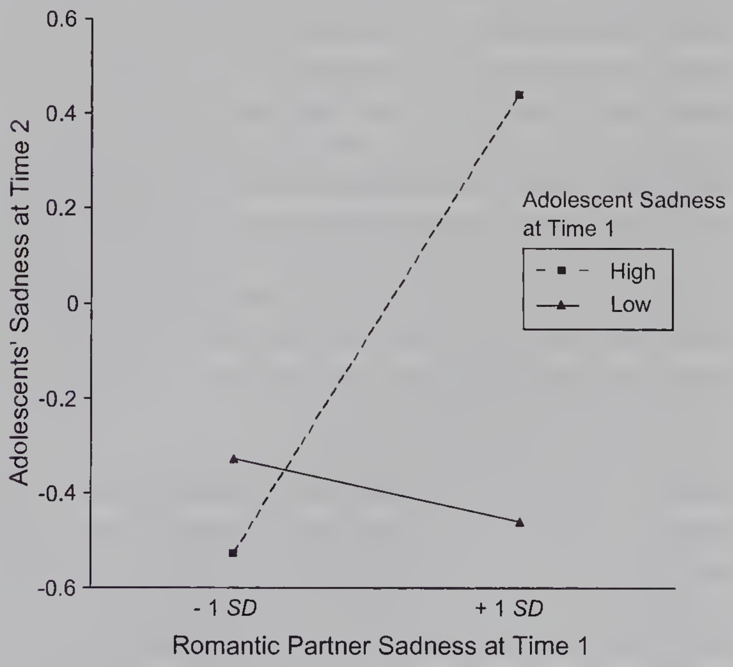

Figure 5. Graph of simple slopes for interactions between adolescent and romantic partner Time 1 peer-rated sadness in predicting adolescents' Time 2 peer-rated sadness with adolescents' sadness as the moderator.

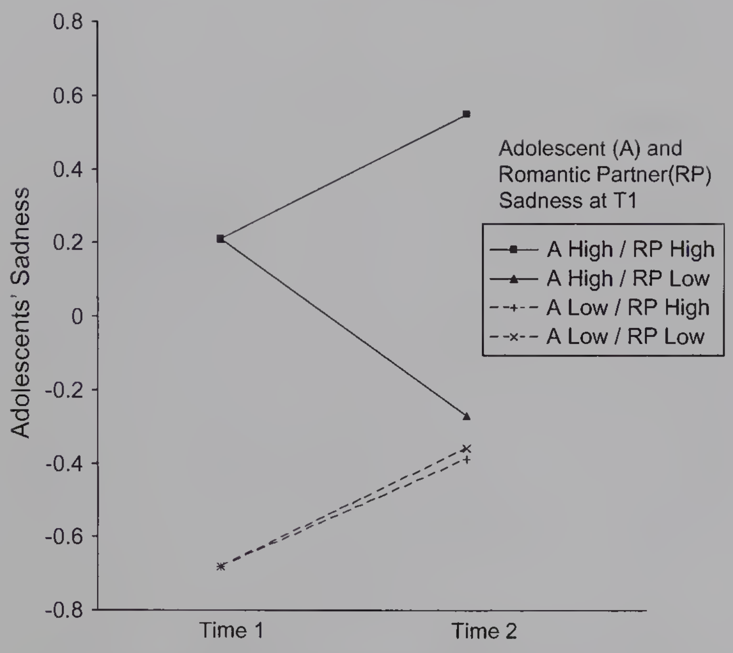

Figure 6. Graph of change patterns in adolescents' peer-rated sadness from Time 1 to Time 2 by combination of adolescent and partner sadness levels at Time 1.

remained stable over time, regardless of their partners' level of functioning. In contrast, low-functioning adolescents changed over time, but only when they dated a high-functioning partner. Low-functioning adolescents (i.e., high on sadness, depressive symptoms, aggression, victimization) who dated a high-functioning partner were indistinguishable at Time 2 from high-functioning adolescents.

For the regression predicting adolescents' self-reported depressive symptoms at Time 2, the interaction between adolescents' and partners' Time 1 depressive symptoms was again a significant predictor (see Table 4). The main effect for partners' Time 1 depressive symptoms was not significant. Results from post hoc probing of the moderating effects of romantic partners are similar to those for peer-rated sadness. Adolescents' Time 1 symptoms predicted their Time 2 symptoms when partners had high ($b = .57, p < .001$) but not low ($b = .28$, *ns*) levels of depressive symptoms at Time 1. These findings suggest that adolescents who dated partners who were low on depressive symptoms changed more than those who dated partners who were high on symptoms.

Results from post hoc probing of the moderating effects of adolescents' initial symptom levels were similar to those for peer-rated sadness. Romantic partners' Time 1 depressive symptoms predicted adolescents' Time 2 depressive symptoms, but only for adolescents who were initially high on symptoms, $b = .75, p < .05$ for high symptoms and $b = -.52$, *ns* for low symptoms. Among adolescents who were initially high on depressive symptoms, those who dated a low-symptom partner reported fewer depressive symptoms at Time 2 than those who dated a high-symptom partner.

Aggression. Romanic partners' relational aggression at Time 1 was not directly associated with adolescents' Time 2 relational aggression. However, the interaction between adolescents' and partners' Time 1 relational aggression was a significant predictor (see Table 4). Results from the post hoc probing of the moderating effects of romantic partners' Time 1 relational aggression were similar to those found for self- and peer-rated depressive symptoms. Adolescents' relational aggression at Time 1 predicted their aggression at Time 2 when partners were high but not low on relational aggression, $b = .20, p < .05$, and $b = -.15$, *ns*, respectively. These findings suggest that adolescents who dated partners who were initially low on relational aggression changed more than those who dated partners who were initially high on relational aggression.

Results from post hoc probing of the moderating effects of adolescents' Time 1 relational aggression were similar to those reported for self- and peer-rated depressive symptoms. Romantic partners' Time 1 relational aggression predicted adolescents' Time 2 relational aggression, but only for adolescents who were initially high on aggression, $b = .21, p < .05$ for high aggression and $b = -.13$, *ns* for low aggression. Among adolescents who were initially high on relational aggression, those who dated a low-aggressive partner were less aggressive at Time 2 than those who dated a high-aggressive partner.

Neither romantic partners' physical aggression at Time 1 nor the interaction between romantic partner and adolescents' physical aggression was associated with participants' Time 2 physical aggression (see Table 4).

Victimization. Although romantic partners' relational victimization at Time 1 was not directly associated with adolescents' Time 2 relational victimization, the interaction between adolescents' and partners' Time 1 relational victimization was a significant predictor (see Table 4). Adolescents' relational victimization at Time 1 predicted their victimization at Time 2 when partners were high but not low on relational victimization, $b = .36, p < .05$ and $b = -.24$, *ns*, respectively. These findings suggest that adolescents who dated partners who were initially low on relational victimization changed more than those who dated partners who were initially high on relational victimization.

Results from post hoc probing of the moderating effects of *adolescents'* Time 1 relational victimization indicated that romantic partners' Time 1 relational victimization predicted adolescents' Time 2 relational victimization, but only for adolescents who were initially high on victimization, $b = .36$, $p < .05$ for high and $b = -.22$, *ns* for low victimization. Among adolescents who were initially high on relational victimization, those who dated a partner low on victimization were less victimized at Time 2 than those who dated a partner high on victimization.

As with physical aggression, neither romantic partners' physical victimization at Time 1 nor the interaction between romantic partner and adolescents' physical victimization was associated with participants' Time 2 physical victimization after controlling for target participants' and best friends' Time 1 levels of victimization (see Table 4).

Discussion

This study is among the first to demonstrate the significance of partner selection and socialization processes in adolescents' romantic relationships. Using a longitudinal design, prerelationship similarities between young adolescent dating partners were isolated to examine patterns of partner selection. Next, we assessed romantic partner socialization by predicting changes in adolescents' psychosocial functioning over time as a function of partners' prerelationship characteristics. The findings suggest that romantic selection and socialization processes are operating even as youth are just beginning to participate in romantic activities, develop cross-sex interaction skills, and construct their identities as romantic partners (Brown, 1999; Connolly et al., 2004).

Partner Selection

Prerelationship similarities detected across both peer and self-report provide compelling evidence of young adolescents' attraction to partners who share comparable levels of social standing, appearance, and depressive symptoms. These results extend prior experimental findings that similarity is predictive of interpersonal attraction (Byrne, 1971). Similarities in peer-rated attractiveness and body appeal suggest that prior reports of similarity between partners' ratings of their own attractiveness reflect more than correspondence in self-perceptions (e.g., Feingold, 1988). Likewise, similarities in self-rated depressive features suggest that young romantic partners view themselves as comparably depressed.

The pattern of selection findings was not entirely as predicted and could underscore a distinction between two types of attraction involved in relationship formation: attraction based on similarity (Byrne, 1997; Feingold, 1988) and attraction based on broad appeal (Newcomb, Bukowski, & Pattee, 1993). Although high levels of physical attractiveness and social status have broad-based appeal, the current findings suggest that adolescents, like adults, typically pair with romantic partners who share similar levels on these dimensions (Feingold, 1988; Folkes, 1982; Hendrick & Hendrick, 1992). Adolescents also paired with partners who shared similar levels of depressive features. Whereas status and attractiveness have broad-based appeal, depressive features may only be attractive to those sharing similar characteristics (Rosenblatt & Greenberg, 1988; Wenzlaff & Prohaska, 1989). Swann and colleagues have speculated that pairing with similarly depressed partners serves to verify individuals' self-image (Giesler & Swann, 1999; Swann, 2004). The aggregation of similarly depressed youth has been noted in peer groups and close friendships during early to middle adolescence (Hogue & Steinberg, 1995; Mariano & Harton, 2005; Stevens & Prinstein, 2005) and roommate and dating relationships during late adolescence (Joiner & Katz, 1999; Katz, Beach, & Joiner, 1999). The current study extends these findings to early romantic development. Additional work is needed to pinpoint the basis of similarity. Given the parallels between young adolescents' friend and romantic relationships and the nesting of both relationships within peer groups, prerelationship similarities in depressive features could reflect peer group as well as dyadic influences.

We had expected that depressive and aggressive features would each be differentially attractive to youth and result in prerelationship similarities on both characteristics. However, we found no evidence that either physical or relational aggression led to assortative pairing. One explanation for these results is that aggression may have broad-based rather than differential appeal. Some studies suggest that aggression becomes increasingly attractive to young adolescents regardless of their own levels of aggression (Bukowski, Sippola, & Newcomb, 2000; Pelligrini & Long, 2003). Perhaps this also includes romantic attraction, in which case the general attractiveness of aggression would make selective pairing less likely to occur. The apparent absence of selective pairing on physical aggression could also reflect general developmental declines in the prominence of physical aggression in adolescent peer relationships (Nagin & Tremblay, 2005; Tremblay, Hartup, & Archer, 2005). That friend dyads in this study were similar on relational but not physical aggression supports this idea. In addition, physical aggression is more common among males and could be more appealing to females seeking male partners than vice versa (Pelligrini & Long, 2003;

Tremblay et al., 2005). Sample limitations precluded testing for gender-specific selection criteria, but their presence could have attenuated any selection effects for aggression.

Overall, the pattern of findings on partner selection suggests that similarity is important to young adolescents' romantic pairing, but only for certain characteristics, and that the pattern of attraction is similar to but not identical to that among friends. The developmental course of these selection criteria within and across relationships warrants additional attention. Patterns of romantic selection could vary according to developmental shifts in social and personal needs (Bukowski et al., 2000). Some features, such as physical attractiveness, could remain important, whereas others, such as intimacy and conflict skills, could gain significance. As the nature of adolescents' relationships change, the allure of some partner characteristics could wane in favor of others that better serve their needs.

Partner Socialization

Romantic partners' prerelationship characteristics predicted change in adolescents' functioning in various domains, including peer popularity, depression, relational aggression, and relational victimization. Of these, only popularity and depressive symptoms were important to partner selection. This pattern of findings suggests that partners need not be similar to adolescents in order to be influential.

Overall, the results from analyses examining romantic partner socialization add to the literature on peer influence in two important ways. First, they provide evidence for the significance of both friends and romantic partners to adolescent adjustment. Although best friendships were already formed at the time of our initial assessment, friend characteristics remained important predictors of adolescents' physical attractiveness, depressive symptoms, relational aggression, and relational victimization. Yet even with a conservative data analytic strategy that controlled for co-occurring best friend socialization, romantic partner characteristics emerged as significant predictors of changes in adolescents' psychosocial functioning. These findings lend credible support to theoretical assertions that romantic partners are unique and significant socializing agents (Collins, 2003).

Second, our results suggest that whether and how romantic partners affect adolescent functioning depends on characteristics of both adolescents and their partners. No partner characteristics were directly predictive of adolescents' functioning over time. This could partly reflect the stability of the characteristics assessed in this study. The small amounts of observed change in adolescents' functioning could have made it difficulty to detect any direct effects of romantic partner characteristics. Nonetheless, estimates of additive peer socialization typically range from nonsignificant to modest. Recent research on deviant peer influence suggests that these main effect models are overly simplistic, as youth vary in both their power to influence and their susceptibility to be influenced (e.g., Dishion & Dodge, 2005; Hartup, 2005). The current findings are consistent with this tenet.

Across multiple outcomes, adolescents who dated high-functioning romantic partners tended to change more than those who dated low-functioning partners, and partner characteristics were more predictive of change for low- versus high-functioning adolescents. Detecting these patterns required separate analyses of the moderating effects of adolescents' and partners' prerelationships functioning. Putting the two sets of analyses together illustrated a consistent pattern in which low-functioning adolescents appeared to benefit from dating high-functioning partners. Low-popular adolescents who dated a high-popular partner gained more popularity over time than the other three groups of adolescents. This particular finding is consistent with prior assertions that early romantic relationships serve to establish adolescents' status and popularity in the peer group (Brown, 1999). Interestingly, already popular adolescents did not seem to suffer much for dating lower popular partners, suggesting that high-popular partners could be particularly important to status grading, at least among young adolescents.

A similar pattern was found for the more problem-oriented outcomes. Only adolescents who dated high-functioning partners showed significant change over time, and romantic partner characteristics only predicted change for low-functioning adolescents. When predicting depression, sadness, relational aggression, or relational victimization, adolescents who coupled with partners who had fewer problems showed more positive changes in these areas than those who coupled with partners with more problems. Among adolescents who dated high-functioning partners, those who initially had more problems were indistinguishable at Time 2 from those who initially had few problems. These findings raise the interesting possibility that high-functioning partners could help mitigate the symptoms of more poorly adjusted youth. Similar findings have been noted among adult couples where patterns of childhood conduct disorder appear to be disrupted by the presence of supportive, nondeviant partners (Laub, Nagin, & Sampson, 1998; Quinton, Pickles, Maughan, & Rutter, 1993; Werner & Smith, 2001). In general, however, findings indicative of buffering effects are rare in the peer literature and highlight the potential for healthy peer influence at an important juncture in psychosocial development.

Additional research is needed to explain how certain adolescents with psychosocial problems pair with and benefit from high-functioning partners. It seems logical that "mismatches" would be more likely to occur on characteristics for which assortative pairing is less likely. Even within the group of characteristics for which assortative pairing is common, there could be individual differences in their relative importance, leading to less similarity on certain characteristics than others. Regardless of how mismatches occur, partner socialization could be stronger in areas that are salient to interpersonal functioning at a given age. Specifying the underlying pathways and mechanisms of these processes over the course of romantic development is an important task for future studies.

The significant stability found for adolescents who dated low-functioning partners also merits further inquiry. Within this group, the reasons for stability could vary between those who were initially high and low functioning. High-functioning adolescents could be relatively unaffected by the problems of their low-functioning partners (Adams et al., 2005). On the other hand, the stability of low-functioning adolescents with low-functioning partners echoes findings in the deviancy training literature, which indicate that psychosocial problems thrive in dyads where both youth are experiencing similar problems (Dishion, McCord, & Poulin, 1999). Our findings are consistent with these interpretations but did not directly test them. Hence, additional research is needed to examine differential reasons for stability among youth who date low-functioning partners.

This study is among the first to offer evidence that romantic partner characteristics affect the psychosocial functioning of young adolescents. The potential for partner socialization across diverse domains of functioning at this age is striking given that early romantic relationships tend to be relatively short lived and low in intimacy. Longer term studies with larger samples are needed to replicate the current findings, assess their duration, and examine potential carry over to subsequent romantic relationships. This information is critical to understanding trajectories of romantic development and their interface with psychosocial functioning. Assessing indices of positive adaptation (e.g., self-esteem, academic achievement, prosocial activity) will also be useful for understanding how romantic partners could promote development and well-being. Addressing these questions will require more detailed knowledge about the partner characteristics that are salient at different phases of romantic development. As noted earlier, there are likely to be age-related shifts in the salience of selection criteria. Similarly, the relative influence of various partner characteristics is likely to change with romantic development. For example, as romantic relationships become more intimate, partners' ways of seeking and providing support or of managing disagreements could become more potent socializing characteristics. Changes in which characteristics predict changes in functioning could also reflect shifts in adolescents' social activities, including age-related trends to engage in substance use or other health-risk behavior.

Finally, it is important to note that there are likely multiple ways in which romantic partner socialization could occur. The current study focused on estimating socialization effects within single domains, such as predicting changes in adolescents' depressive symptoms from partners' initial levels of depressive symptoms. Other, more complex processes could also be operating. For example, a given partner characteristic could influence a different adolescent characteristic. Similar findings have been noted in the adult literature, where partner support has been shown to disrupt patterns of childhood conduct disorder (Laub et al., 1998; Quinton et al., 1993). Similarly, coupling with an aggressive partner predicts increases in one's depressive symptoms (Simonelli & Ingram, 1998), and these problems could even cooccur in ways that shape both partners' behaviors (Kim & Capaldi, 2004). Such findings suggest a need for additional research to address the socialization effects of partner characteristics across domains of functioning.

Limitations and Future Directions

Several factors should be considered when interpreting the findings from this study. First, we have discussed our longitudinal findings in ways that suggest that romantic partner characteristics influence adolescents' subsequent functioning. Although our results are consistent with peer socialization processes, the data are nonexperimental and thus inconclusive with respect to causal explanations. For example, some adolescents may already be headed toward change, and their selection of certain types of partners may be a signal rather than a cause of change.

Other limitations of the current study pertain to the nature of the sample. First, only 30% of the participants from the larger data collection met our inclusion criteria of being in a romantic relationship at Time 2. This was a select group of youth, who, on average, were more physically fit, good looking, and popular, as well as less depressed and less victimized than their nondating peers. Their prevalence, however, is similar to base rate estimates of romantic relationships in this age group (e.g., Carver & Udry, 2003; Giordano, Manning, & Longmore, 2006). Although involvement in romantic relationships is not necessarily the norm for middle school students, our findings could still be relevant to the broader population of young adolescents. After all, adolescents are romantically active even when not in relationships. They are preoccupied with romantic issues and intensely aware of romantic relationship dynamics (Connolly et al., 2004).

Our sample was also restricted to middle school students who dated other middle school students at their school. Although this inclusion criterion was necessary to identify partner characteristics, the exclusion of adolescents dating peers from another school or age group could have influenced our findings. Likewise, our sample was limited to youth with same-sex friendships and other-sex romantic partners. Little is known about friend and peer group influences on romantic relationship formation in sexual minority youth. However, it seems reasonable that differences in the availability and identification of potential romantic partners for sexual minority adolescents would have implications for partner selection and socialization processes.

Overall, sample constraints in this study are balanced against numerous methodological strengths, including the assessment of diverse aspects of psychosocial functioning prior and subsequent to romantic relationship initiation, utilization of multiple reporters, isolation of friend and partner characteristics, and assessment of multiple moderators of romantic partner socialization. These assets allowed us to identify discrete patterns of selective pairing and identify ways in which the pairing of certain adolescent and partner characteristics predicts changes in adolescent adjustment. It is hoped that these findings will stimulate additional research on romantic partner characteristics, as they seem important for understanding individual differences in links between romantic involvement and adjustment.

Adrenocortical Underpinnings of Children's Psychological Reactivity to Interparental Conflict

Patrick T. Davies and Melissa L. Sturge-Apple

E. Mark Cummings
University of Notre Dame

This study examined interrelationships among children's cortisol reactivity and their psychological reactivity to interparental conflict in a sample of 208 first graders (mean age = 6.6 years). Assessments of children's psychological reactivity to conflict distinguished among their distress, hostile, and involvement responses across multiple methods (i.e., observation, questionnaire) and informants (i.e., observer, parent). Relative to other forms of conflict reactivity, children's distress responses to interparental conflict were consistent, unique predictors of their elevated cortisol reactivity to interparental conflict even after inclusion of demographic factors as moderators and covariates. Moderator analyses further revealed that associations between distress and elevated cortisol levels in response to interparental conflict were particularly pronounced when children exhibited high levels of involvement in conflicts.

Understanding how children respond to interparental conflict is a pressing priority for public health (National Institutes of Health, 2003. Interparental conflict increases children's vulnerability to a wide range of behavioral, emotional, and social problems. In attempting to identify the processes associated with the risk experienced by children from high-conflict homes, conceptual models have underscored the significance of children's responses to conflict across multiple levels of analysis (Davies & Cummings, 2006). For example, emotional security theory (EST) regards children's elevated distress responses to conflict as developing from repeated exposure to destructive interparental conflict and, in turn, increasing the likelihood of psychological problems (Davies & Cummings, 1994). At another level of analysis, research on children's physiological reactivity to conflict has elucidated pathways between interparental conflict history and child adjustment problems (e.g., see review by Katz, 2001).

The approach commonly shared by the psychological and psychophysiological research traditions involves analyzing children's responses to conflict at one level of analysis (e.g., psychological) in isolation from children's response patterns at other levels of analysis (e.g., physiological). For example, empirical tests of psychological theories of interparental conflict have primarily focused on the analysis of behavioral and social-cognitive reactions to interparental conflict to the relative exclusion of physiological assessments (Davies & Cummings, 1994; Grych & Fincham, 1990). Likewise, studies conducted on children's physiological functioning in the context of adult or parental conflict are commonly rooted in a different body of literature addressing children's physiological reactivity to broad array of stressful events (Katz, 2001). Therefore, little is known about the interplay among children's psychological and physiological reactivity to interparental conflict.

In reflecting the repeated calls to integrate children's physiological and psychological responses to family stress (Cummings, Davies, & Campbell, 2000; Fox, Hane, & Perez-Edgar, 2006; Katz, 2001), Katz concluded: "It is only through integrating our understanding of both biological and behavioral processes that we can get a complete picture of the effects of marital conflict on the whole child" (p. 207). Therefore, although dissociations between physiological and

psychological indices of functioning are common in the literature, fully understanding children's responses to conflict at multiple levels of analysis requires further examination of how indices of physiological reactivity to conflict correspond concurrently with comparable assessments of psychological responses to conflict (Fox et al., 2006).

To address the paucity of research on the relationship between children's physiological and psychological reactivity to interparental conflict, we examine associations between children's behavioral reactivity and their limbic-hypothalamic-pituitary-adrenocortical (LHPA) system reactivity to interparental conflict. Through its role as a second wave of autonomic responding to stress (Cahill & McGaugh, 1998), the LHPA axis is regarded as a useful means of advancing an understanding of children's reactivity to interparental conflict (Saltzman, Holden, & Holahan, 2005). In response to stressful events, components of the limbic system (e.g., amygdala, hippocampus) involved in processing aversive stimuli modulate the release of corticotropin-releasing factor (CRF) by the hypothalamus. CRF, in turn, activates the adrenal gland to secrete cortisol by stimulating the pituitary gland to produce and release adrenocorticotropic hormone into the bloodstream. Increases in cortisol in response to stress mobilize energy (e.g., glucose, oxygen), increase cardiovascular activity, and modulate the processing, learning, and memory consolidation of emotionally significant events (Cahill & McGaugh, 1998; Gunnar & Vazquez, 2006). In accord with the role that the LHPA axis plays in allocating resources to process and cope with stressful events, cortisol reactivity may be a critical component of children's responses to the stress of witnessing interparental conflict. Thus, the purpose of this study was to examine the concomitant correspondence between children's cortisol reactivity to interparental conflict and three of the most common forms of children's responses to conflict: distress, hostility, and involvement (Cummings & Davies, 1994).

EST provides a foundation for expecting associations between children's behavioral and physiological responses to interparental conflict. According to EST, preserving a sense of security is an important goal for children in contexts of interparental conflict (Cummings & Davies, 1996). When children witness interparental conflict, elevations in their distress characterized by anxiety, vigilance, and emotional upset are theorized to be one of the most reliable barometers of children's insecurity in the interparental relationship. Drawing on the role of the LHPA axis in marshalling resources to cope with threatening events, EST proposes that distress indicative of children's concerns about security may be linked with changes in the ability of the LHPA axis to mount physiological responses to interparental conflict. These individual differences in the LHPA axis are hypothesized to insidiously undermine children's physical and mental health over time (Davies, Winter, & Cicchetti, 2006).

Because EST offers little guidance with regard to the nature of the proposed link between behavioral and cortisol reactivity, theories on the physiological underpinnings of individual psychological functioning may sharpen predictions on the interplay between children's psychological and cortisol reactivity to interparental conflict. First, consistent with the emphasis on distress in EST, some physiological conceptualizations postulate that elevated cortisol reactivity to stressful events is most likely to occur when children are predisposed toward exhibiting submissive behavioral reactions characterized by high levels of emotional distress, anxiety, and inhibition (e.g., Fox et al., 2006; Kagan, Reznick, & Snidman, 1998; Spangler & Grossmann, 1993). Thus, in the context of understanding children's responses to interparental conflict, this "distress specificity" model would predict that children's distress should evidence unique and specific associations with cortisol reactivity relative to other forms of behavioral responding (i.e., involvement, hostility). Second, the negative affect hypothesis postulates that greater cortisol reactivity underlies more general forms of negative emotional responses to stressful events, including irritability and hostility (Spangler & Grossmann, 1993). Therefore, in contrast to the distress specificity model, the prediction of the negative affect hypothesis is that both distress and hostility would evidence stronger relations to elevated cortisol reactivity, especially in relation to involvement. Third, within a general arousal model, any type of behavioral activation or engagement with the stressor is expected to be associated with elevated cortisol reactivity (see Gunnar & Vazquez, 2006). Thus, as forms of behavioral activation, another hypothesis is that distress, hostility, and involvement may each be linked with greater cortisol reactivity.

Some support is evident for the predictions of the distress specificity model. Children with elevated internalizing symptoms have been shown to exhibit concurrent elevations in cortisol reactivity to mild laboratory stressors (e.g., Ashman, Dawson, Panagiotides, Yamada, & Wilkinson, 2002; Granger, Weisz, & Kauneckis, 1994). Tests of the coupling of behavioral and adrenocortical activity in response to the same stressor also provide support to the distress specificity hypothesis. For example, children's behavioral distress in response to social stressors (e.g., caregiver separation, transition to day care) have been contemporaneously linked with greater cortisol reactivity to social stressors (e.g., caregiver separation, transition to day care) (Dettling, Gunnar, & Donzella, 1999; Gunnar, Larson, Hertsgaard, Harris, & Brodersen, 1992). Likewise, patterns of distress reflecting insecure attachment patterns are associated with children's greater cortisol reactivity to the series of separations and reunions during the strange situation (Hertsgaard, Gunnar, Erickson, & Nachmias, 1995; Spangler & Grossmann, 1993).

At the same time, other studies do not definitively support the distress specificity hypothesis. Inclusion of indicators of anger in assessments of distress in some of the studies described above cannot disentangle the distinct associations between forms of negative emotional and adrenocortical reactivity as outlined in the distress specificity hypothesis (e.g., Dettling et al., 1999). In fact, some studies have revealed that indices of child aggression, anger, and global negative affect in child care settings were correlated with increases in cortisol activity across the day (Dettling, Parker, Lane, Sebanc, & Gunnar, 2000; Dettling et al., 1999; Gunnar & Donzella, 2000; Tout, de Haan, Campbell, & Gunnar, 1998). Therefore, in support of the negative affect model, one alternative hypothesis would be that high levels of cortisol reactivity are coupled with any form of negative reactivity to interparental conflict. Given that some of the studies on preschool adjustment to day care have also reported that impulsive and approach behaviors are associated with elevated child cortisol reactivity (e.g., Dettling et al., 1999), the general arousal hypothesis that any effortful response to interparental conflict may covary with elevated cortisol is also plausible.

In light of inconsistencies in associations between behavioral and adrenocortical reactivity to other stressful events, rigorously testing the distress specificity hypothesis hinges on examining its relative viability in relation to the negative affect and general arousal hypotheses.

Thus, the present study simultaneously examines the specificity and commonality of patterns of associations between children's distress, hostile, and involvement responses to interparental conflict and elevated cortisol reactivity to interparental conflict. Consistent with the organizational perspective on development (Cicchetti & Tucker, 1994), the associations between any form of behavioral responding and adrenocortical reactivity may depend on children's broader patterns of behavioral responses to interparental conflict. For example, the EST suggests that distress responses may signify more pronounced threats to children's security if they are coupled with high levels of involvement in interparental conflicts (Davies et al., 2006). Accordingly, we also employ moderator models to explore whether associations between distress and cortisol reactivity are moderated by involvement and hostility. Toward the goal of examining the stability of our results, a final step is to examine the role of child and demographic characteristics (i.e., gender, race, blood contamination in saliva samples, medication use, research site) that may alter associations between children's psychological and cortisol reactivity to conflict as covariates and moderators (Cohen et al., 2006; Granger et al., 2007; Hibel, Granger, Cicchetti, & Rogosch, 2007; Loney, Butler, Lima, Counts, & Eckel, 2006).

Method

Participants

The data for this study were collected from the second measurement occasion of a longitudinal project on children's coping with family stress. The original sample of 235 kindergarten children and their families in the first measurement occasion of the study were recruited through local school districts and community centers at two research sites located in moderate-sized cities in the Northeast and the Midwest. The sample for this study consisted of 208 mothers and their first-grade children. Reductions in the size of the original sample resulted from attrition of families during the 1-year span between measurement occasions ($n = 8$), incomplete data across the three cortisol assessments ($n = 2$), and exclusion of children who were identified as outliers (i.e., ± 3 *SD* from the mean) on cortisol assessments ($n = 8$). Due to the potential effects of psychotropic and glucocorticoid drugs on cortisol levels (Hibel et al., 2007; Masharani et al., 2005), 9 additional children who were taking these medications were excluded from the final sample. Thus, the sample used in this article consisted of 208 mothers and their children. Statistical comparisons of the present sample ($n = 208$) and participants in the larger sample who were excluded from this study ($n = 27$) along 16 demographic (e.g., family income, occupational status, race/ethnicity, marital status, age) variables yielded no significant differences.

Sociodemographic data reflected that the participating families were similar to the households in the counties from which our sample was drawn (i.e., St. Joseph County, IN; Monroe County, NY). Median annual family income of the families was between $40,000 and $54,999. Mothers, on average, completed some college. The majority of the sample of mothers and children were White (75%), followed by smaller proportions of Black (15%), multiracial (7%), and Hispanic (3%) family members. A large percentage of female caregivers reported being the biological parents of their children (95%), followed by relatively smaller percentages of step or adoptive parents (3%), and other types of guardianship (2%). The mean age of the children was 6.6 years (*SD* = 0.52), with 56% of the sample consisting of girls (n = 117) and 44% consisting of boys (n = 91). Mothers, fathers, and children lived in the same household for an average of 6.4 years (*SD* = 1.09).

Procedures

Following the completion of two visits to the laboratory during the first measurement occasion, mothers and children attended two more laboratory visits at one of the research sites during second measurement occasion 1 year later. Data for the current study were drawn from the second visit of the second measurement occasion (i.e., the fourth family visit to our laboratory). The laboratories at each site were designed to be comparable in size and quality and included: (a) an observation room that was designed to resemble a family room (e.g., couch, pictures, lamps, end tables) and equipped with audiovisual equipment to capture family interactions and (b) interview rooms for completing confidential survey measures. The research was approved by the Institutional Review Boards at both sites prior to conducting the study.

Simulated phone argument task (SPAT). During the visit, children and their mothers participated in the SPAT to assess child reactivity to interparental conflict. During this procedure, children witnessed a live simulated conflict and resolution between their parents over the telephone. Each exchange lasted approximately 1 min and was interspersed by a 3-min free period to assess prolonged or delayed responses of children. The conflict script revolved around a relatively trivial disagreement regarding whether the father had completed a task requested by the mother (i.e., stopped at the store or made a phone call or an appointment). The mothers were instructed to convey mild irritation, frustration, and anger toward their partner as they normally would at home. Although the simulation indicated to the child that the father was on the other end of the phone, an experimenter was actually on the phone feeding the mother the lines from the script. Videotaped records were later coded for child overt reactivity to the interparental conflict. For ethical purposes of allaying any child distress, the resolution with the father over the telephone consisted of mother communicating a moderate level of understanding, caring, and warmth in her tone of voice. Interspersed between the free period following the conflict and the resolution were two 5-min interviews with children designed to assess their reactions to the conflict and resolution, respectively.

Several procedures were instituted during a presimulation training session to maximize the validity of the SPAT. First, to maximize the accuracy of the simulations, mothers listened to a standard, audiotaped sample of the conflict and resolution and practiced the script with the experimenter until they were able to convey accurately the content and affective tone of the exchanges. Moreover, in feeding the mother the lines during the procedure, the experimenter simulated the affective tone and level for the mother to emulate. Second, to increase the ecological validity of the exchanges, mothers: (a) scheduled the visit during a time in which the father was accessible by phone, (b) chose one of the three script options that most realistically reflected the nature of interparental activities, and (c) had the opportunity to alter the scripts to reflect the content and nature of actual interparental conflicts and resolutions that occur in the home. Script changes were only implemented if they did not significantly alter the intensity, meaning, and affective tone of the disagreement or resolution. Thus, this procedure provided important controls over the nature of interparental conflict stimuli while at the same time presenting conflicts that were for all purposes live and real from the observing child's perspective. The validity of the SPAT is supported by associations between children's distress reactions to the simulated conflict and their exposure to family conflict and their concurrent and prospective psychological problems (e.g., Davies, Cummings, & Winter, 2004).

Salivary cortisol collection. Saliva samples were collected from the children at three points during the simulated conflict procedure to obtain cortisol measures. Cortisol levels tend to evidence more gradual declines during the afternoon and evening hours than during the morning hours (Knutson et al., 1997; Stansbury & Gunnar, 1994). Thus, to limit the effects of time of day on cortisol assessments, sample collection times for cortisol were, with one exception, collected in the afternoon or early evening. Average sampling time for pretask cortisol occurred at 3:50 p.m. (*SD* = 2 hr 1 min).

In the initial 20 min of the visit prior to the collection of the pretask saliva sample, the experimenters developed rapport with the families, obtained parental consent and child assent, and invited children to play with toys to get reacquainted with the laboratory. While the mother was learning the script for the SPAT, the children then followed conventional sampling procedures in preparation of saliva sampling procedures (Schwartz, Granger, Susman, Gunnar, & Laird, 1998). Children rinsed their mouths with water prior to the baseline assessment to limit the undue influence of various contaminants during the assay process. Following a 7-min period in which they were invited to play with toys, children chewed Trident original flavor sugarless gum for approximately 3 min to stimulate saliva flow immediately prior to saliva collection. The pretask sample was then collected prior to the simulated conflict by having children expurgate through a plastic straw directly into a 20-ml collection vial.

Two postconflict saliva samples were also obtained to assess trajectories of cortisol change across three assessments. No definitive guidelines are available for precisely identifying the timing of peak cortisol levels following stressors. However, a recent meta-analysis of cortisol functioning revealed that cortisol levels across 10-min periods following the stressor were highest during the 21- to 30-min and 31- to 40-min epochs than any other 10-min period (Dickerson & Kemeny, 2004). Therefore, the two postconflict saliva samples were obtained approximately 25 and 35 min after the simulated conflict to correspond with the midpoints of the two 10-min peak periods of cortisol reactivity to stressors. Consistent with the preconflict sampling procedures, children chewed Trident original flavor sugarless gum to stimulate saliva flow and then expectorated through a plastic straw directly into a 20-ml collection vial. In the interim between the SPAT and the two postconflict sampling procedures, children were invited to play with toys in the room to limit extraneous stress and challenge that may result from inclusion of tasks or measures. The three saliva samples were immediately stored at −36°C until it was shipped on dry ice to Salimetrics LC (State College, PA).

Reports of child reactivity to conflict. Following a brief break after the SPAT, mothers completed a measure of children's behavioral reactivity to interparental conflict in the home as part of a battery of questionnaires.

Measures

Observer ratings of child behavioral reactivity to conflict. Children's behavioral reactions to the simulated conflict during SPAT were coded for distress, hostility, and involvement. To assess children's behavioral reactivity to interparental discord, judges coded the presence of specific types of the three behaviors (i.e., distress, hostility, involvement) for eight 30-s intervals during the 4-min videotaped segment of the conflict and postconflict periods. Specific behaviors indicative of distress reactions included: (a) freezing—tense, motionless, or "fixed in place" for 5 or more seconds; (b) anxiety—expressions of anxiety through facial expressions and/or physical gestures; and (c) verbal concern—verbalizations of concern about the interparental conflict. Measures of hostile behavior consisted of: (a) anger—facial expressions or postures reflecting anger, (b) interpersonal aggression—verbal or physical hostility directed toward the self or others, and (c) object aggression—verbal or physical aggression directed toward objects. Finally, specific indicators of involvement were as follows: (a) comforting the parent—verbal or physical attempts to comfort or mediate the conflict, (b) inquiries about parent feelings or relationships—questions about the emotional state of the parent or quality of the interparental relationship (e.g., "Mom, are you okay?" "Is dad mad?"), and (c) triangulation—intervention strategies that reflect efforts to ally with one parent against the other parent. Although codes within each composite were designed to economically capture complementary dimensions (i.e., distinct with modest overlap) of the larger construct, codes were not mutually exclusive. Therefore, multiple behavioral codes (e.g., anger, interpersonal aggression) could be rated as present within any interval. Frequency counts of the specific indicators of each of the three respective constructs were summed together to form composites of distress, hostile, and involvement behaviors. To establish reliability, two coders independently coded 25% of the videotapes. Intraclass correlation coefficients, reflecting interrater agreement in the frequency counts of each of the nine specific behavioral codes ranged from .64 to 1.0. Average intraclass coefficients were .86 for indicators of distress, .74 for the hostility codes, and .91 for the involvement behaviors.

Maternal reports of behavioral reactivity to conflict. Mothers completed questionnaire items derived from the Security in the Marital Subsystem – Parent Report Inventory (SIMS – PR) to obtain indices of children's distress, hostile, and involvement responses to conflict in the home over the last year that were comparable to behavioral codes in the SPAT (Davies, Forman, Rasi, & Stevens, 2002). For the current report, three modified versions of the SIMS – PR subscales were utilized. The Distress (or Emotional Reactivity) scale consists of six items that reflect anxiety, distress, and submissiveness (i.e., "appears frightened," "keeps very still [almost as if he or she is frozen]," "still seems upset after we argue," "appears upset," "tries to hide feelings," "repeatedly brings up questions and concerns about arguments after its over"). The Hostility scale contains five items that characterize angry and aggressive reactions to interparental conflict in the home (i.e., "yells at family members," "says unkind things to family members," "starts hitting, kicking, slapping, or throwing things at family members," "appears angry," "causes trouble"). The Involvement scale is composed of five items that index children's behavioral intervention in interparental conflicts and their aftermath (e.g., "tries to help us solve the problem," "tries to comfort one or both of us," "watches and listens very closely," "tells us to stop arguing," "gets involved in the argument"). In further support of the factor structure of the SIMS – PR, an exploratory factor analysis of the 16 items generated a three-factor solution that supported the specification of each of the items onto three respective subscales. Internal consistencies for the Distress, Hostility, and Involvement scales, as indexed by alpha coefficients, were .78, .78, and .73, respectively. The validity of the original SIMS – PR scales is supported by its theoretically meaningful associations with children's exposure to family conflict, coping difficulties with family stress, and psychological problems (e.g., Cummings, Schermerhorn, Davies, Goeke-Morey, & Cummings, 2006; Davies, Harold, Goeke-Morey, & Cummings, 2002).

Cortisol. All samples were assayed for salivary cortisol at Salimetrics Inc. in duplicate using a highly sensitive enzyme immunoassay (Salimetrics, PA). The test used 25 μl of saliva per determination, has a lower limit of sensitivity of 0.003 μg/dl, standard curve range of 0.007 – 1.8 μg/dl, and average intra- and interassay coefficients of variation 5.1% and 8.2%, respectively. Method accuracy, determined by spike recovery, and linearity, determined by serial dilution are 103% and 96%, respectively. Values from matched serum and saliva samples show the expected strong linear relationship, $r(63) = 0.89$, $p < .0001$ (Salimetrics, 2000).

Demographic and child characteristics. Five demographic and child variables were examined as potential covariates or moderators in the model: (a) blood contamination in saliva, (b) child medication use, (c) research site, (d) child gender, and (e) child race. First, to obtain an assessment of blood contamination, saliva samples were assayed for transferrin through immunoassays conducted by Salimetrics. The test, which uses 20 μl of saliva per assay, has a minimum detection limit of 0.12 mg/dl. Mean blood contamination levels (M = 0.33 mg/dl; SD = 0.35 mg/dl; range = .05 – 3.22 mg/dl) in this study were generally comparable to, if not lower than, prior studies (Kivlighan et al., 2004). Second, consistent with prior work (e.g., Hibel, Granger, Kivlighan, Blair, & the Family Life Investigators, 2006), mothers reported on children's over-the-counter and prescription medication use. Children who were taking at least one medication (20%) were compared with children who were medication free (80%). The most frequently used medications included acetaminophen or ibuprofen (6.7%) and nonsteroidal anti-inflammatory drugs (6.7%), followed by relatively lower levels of over-the-counter cough/cold medicine (2.4%), vitamins (2.4%), antibiotics (1.4%), antacids (0.9%), and other medications (2.9%). Third, research site was coded as a dichotomous variable (i.e., Northeast site contrasted with Midwest site). Finally, in addition to examining child gender (i.e., girls contrasted with boys), child race was explored as a fifth potential variable based on prior LHPA axis differences between White and Black adults (Black children contrasted with White children; Cohen et al., 2006).

Results

Descriptive Analyses

Table 1 provides the raw means, standard deviations, and correlations among the focal variables in the primary analyses. Correlations between distress, hostility, and involvement within each method of assessment (i.e., SPAT observation, maternal report) were modest in magnitude (mean r = .20, range = −.03 to .35). As expected, associations among conceptually related constructs (e.g., involvement) derived from different methods were also modest and significant (mean r = .20, range = .15 to .24). Modest correspondence across different informant reports of child psychological distress is very common in developmental and clinical research (De Los Reyes & Kazdin, 2005). As with prior research on child psychological problems, the multiple methods were derived from informants who amassed different types of information about children from different contexts (Achenbach, 2006). Log transformations of the three cortisol measures were used to reduce skewness and normalize distributions prior to the primary analyses, yielding the following means and standard deviations: preconflict (M = −2.44, SD = 0.47), post-I conflict (M = −2.70, SD = 0.44), and post-II conflict (M = −2.75, SD = 0.43).

Preliminary Analyses

The predominant strategy of assessing cortisol reactivity to stressors through the piecewise calculation of difference scores between prestressor and each poststressor cortisol level in analysis of variance or regression models fails to: (a) disentangle measurement error from measures of reactivity and (b) effectively capture individual differences in cortisol trajectories across three or more measurement occasions (Hruschka, Kohrt, & Worthman, 2005). Because growth modeling addresses these limitations (e.g., see Powers, Pietromonaco, Gunlicks, & Sayer, 2006), we assessed the slope of change across the preconflict, post-I, and post-II cortisol assessments through the use of latent growth curve (LGC) modeling.

Given the diurnal rhythm of cortisol, our first step in LGC modeling involved specifying the effects of time of measurement, prior to the inclusion of the main predictors or any covariates or moderators. LGC specification was identical to the model depicted in Figure 1 without the inclusion of the three forms of conflict reactivity as predictors. The model fit the data well, $\chi^2(7, N = 208) = 2.84$, $p = .90$, χ^2/df ratio = 0.41, root mean square error of approximation (RMSEA) = 0.000, comparative fit index (CFI) = 1.00. As an estimate of preconflict cortisol levels, the mean level of the intercept was significantly different from 0 ($\mu_i = -1.60$, $z = 6.37$). The mean slope parameter, which characterizes average, constant change in cortisol across the three assessments, was positive but not significant ($\mu_s = 0.44$, $z = 1.67$). Notably, analyses of the variance for the intercept and slope factors yielded significant individual differences in the initial levels of cortisol ($\zeta_i = 0.18$, $z = 6.60$) and change in cortisol ($\zeta_s = 0.18$, $z = 4.23$). Therefore, the results support our aim of examining associations between individual differences in children's psychological and cortisol responses to interparental conflict.

Primary Analyses

Although associations between behavioral and adrenocortical functioning may reflect bidirectional influences between the systems, our goal was to identify the specificity and uniqueness of associations between children's patterns of behavioral reactivity and their cortisol reactivity. Accordingly, to examine the relative and distinct patterns of correspondence between behavioral and cortisol reactivity, we simultaneously examined children's distress, hostility, and involvement as predictors of cortisol activity in a series of growth models. The first model involved the specification of pathways from SPAT observational ratings of distress, hostility, and involvement to the initial levels (intercept) and change in cortisol in response to the conflict (slope). The model, which is depicted in Figure 1, provided an acceptable representation of the data, $\chi^2(19, N = 208) = 15.34$, $p = .70$, χ^2/df ratio = 0.81, RMSEA = 0.000, CFI = 1.00. Paths between children's behavioral responses and the cortisol slope are of particular relevance in light of our focus on children's cortisol reactivity to conflict. Consistent with hypotheses, children's distress was positively associated with cortisol reactivity to the simulated interparental conflict, $\beta = .23$, $p < .01$. In contrast, hostility and involvement were not associated with initial levels or change in cortisol reactivity.

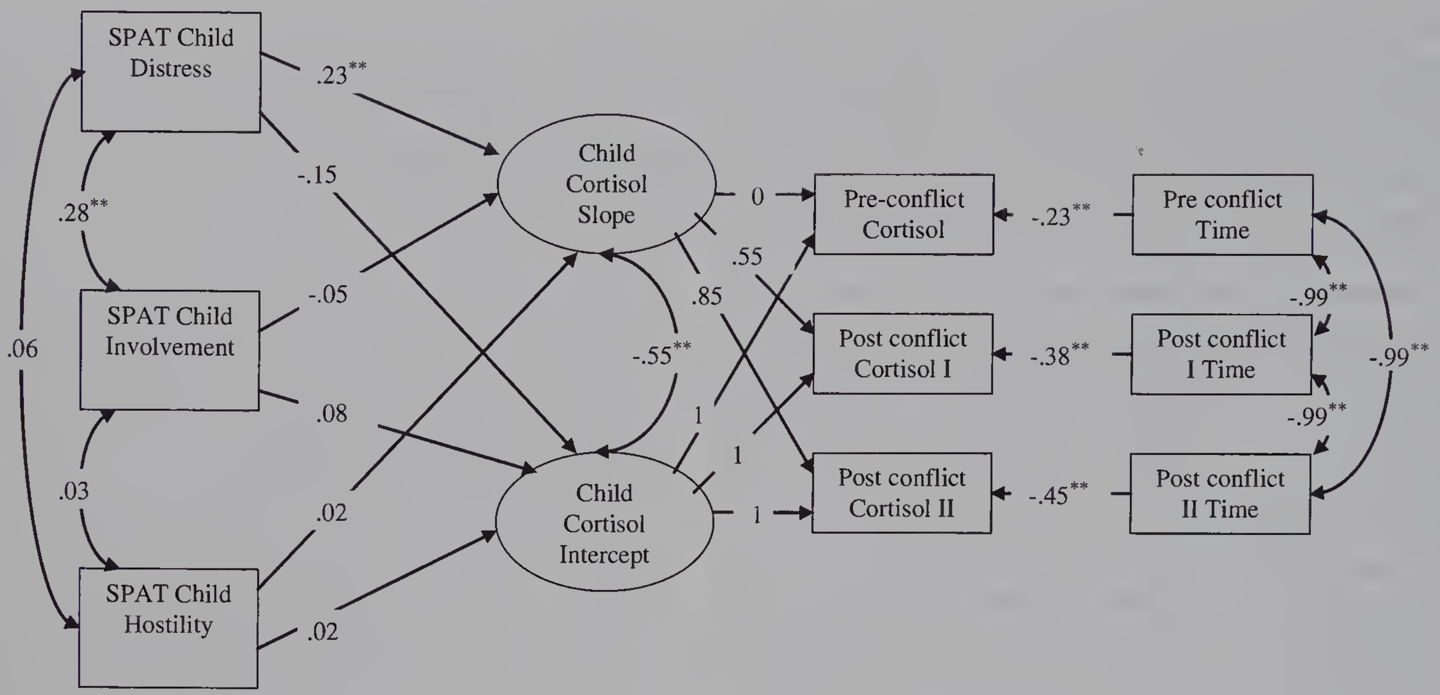

Figure 1. Associations between children's observed psychological reactivity and their cortisol reactivity to the simulated interparental conflict.
Note. SPAT = simulated phone argument task.
$^{**}p < .01$.

As a further test of the specificity of associations, we calculated pairwise parameter comparisons of the magnitude of paths running from each form of child psychological reactivity to child cortisol reactivity. The results indicated that the association between distress and cortisol reactivity was marginally stronger than comparable pathways involving hostility, $z = 1.60$, $p = .055$ (one-tailed), and involvement, $z = 1.60$, $p = .055$ (one-tailed).

To explore the viability of this model for children's psychological reactivity in the home, we also examined associations between maternal reports of children's reactivity to conflict in the home and their cortisol reactivity to the simulated interparental conflict. As shown in Figure 2, the model yielded a good representation of the data, $\chi^2(19, N = 208) = 34.16$, $p = .02$, χ^2/df ratio = 1.80, RMSEA = 0.062, CFI = 0.99. Consistent with the findings from the first model, maternal reports of children's distress responses to interparental conflict in the home were significantly associated with greater cortisol reactivity to conflict, $\beta = .27$, $p < .001$, and lower preconflict levels of cortisol, $\beta = -.18$, $p < .05$. Conversely, dampened cortisol reactivity was related to maternal reports of child hostility, $\beta = -.20$, $p = .01$. Analysis of pairwise comparisons among the pathways running from behavioral reactivity to the cortiso l slope revealed that distress was a stronger predictor of greater cortisol reactivity than either hostility, $z = 3.53$, $p < .01$, or involvement, $z = 3.08$, $p < .01$.

Tests of the Stability of the Primary Findings

As a further test of the generalizability of the results, we examined whether blood contamination in saliva, child medication use, research site, child gender, and child race may serve as both covariates and moderators that alter the nature of associations between children's distress and their cortisol reactivity to conflict. First, for both the SPAT and the maternal report models of child reactivity depicted in Figures 1 and 2, we conducted five additional covariate analyses incorporating paths between each of the five demographic variables and the intercept and slope of child cortisol. Supporting the stability of the findings, all paths between the covariates and the intercept and slope of cortisol were nonsignificant. Moreover, inclusion of the demographic variables did not alter the significant paths between children's distress and child cortisol reactivity for either the SPAT or the maternal ratings of children's responses to conflict. Second, moderator models examined whether the associations between distress and cortisol varied across the five demographic variables. We conducted separate models for each predictor and demographic

$^{*}p < .05$. $^{**}p < .01$.

variable pairing. In these analyses, the main effects of the distress variable and the specific demographic factor along with the two-way interaction term were all included as predictors of the cortisol intercept and slope. The results of the analyses produced no more moderating effects for the five demographic variables (1 of the 20 interactions was significant) than would be expected by chance. In conclusion, the results were consistent across a variety of contextual conditions, including research site, child gender, child race, blood contamination levels, and child medication use.

Child Involvement and Hostility as Moderators of Distress

Guided by our conceptual focus on distress, our final analytic model selectively examined whether associations between distress and child cortisol reactivity to conflict were moderated by children's involvement or hostile reactions to the conflict. Distress, proposed moderator (i.e., either hostility or involvement), and the Distress × Proposed Moderator (i.e., either hostility or involvement) interaction variables were simultaneously estimated as predictors of the cortisol intercept and slope in the LGC analyses. Four separate statistical models were specified for each of the two measures (SPAT, maternal ratings) of the two proposed moderators after centering the predictors to reduce problems with multicollinearity (Aiken & West, 1991). For the sake of brevity, we focus on the results that directly address the paths between moderator terms and cortisol reactivity. Of the four moderator analyses conducted, only the interaction term involving SPAT observations of distress and involvement was a significant predictor of child cortisol reactivity ($B = .07$, $t = 2.38$, $p < .05$). To clarify the interaction in LGC analyses of the SPAT, we followed the procedures outlined by Preacher, Curran, and Bauer (2006) for: (a) plotting regression slopes of child distress at high (1 *SD* above the mean) and low (1 *SD* below the mean) levels of involvement and (b) conducting simple slope analyses to examine whether associations between distress and cortisol reactivity were significantly different from 0 at high (+1 *SD*) and low (−1 *SD*) levels of involvement. As the graphical plot in Figure 3 shows, the association between distress and the cortisol slope is particularly pronounced at high rather than low levels of involvement. In support of this interpretation, simple slope analyses indicated that observations of child distress predicted greater cortisol reactivity when levels of child involvement in the conflict were high ($B = .15$, $t = 4.24$, $p < .001$) but not low ($B = -.01$, $t = 0.25$, $p = ns$).

Discussion

Various conceptualizations of children's coping with interparental conflict and children's psychobiological reactivity to social stressors converge to highlight the

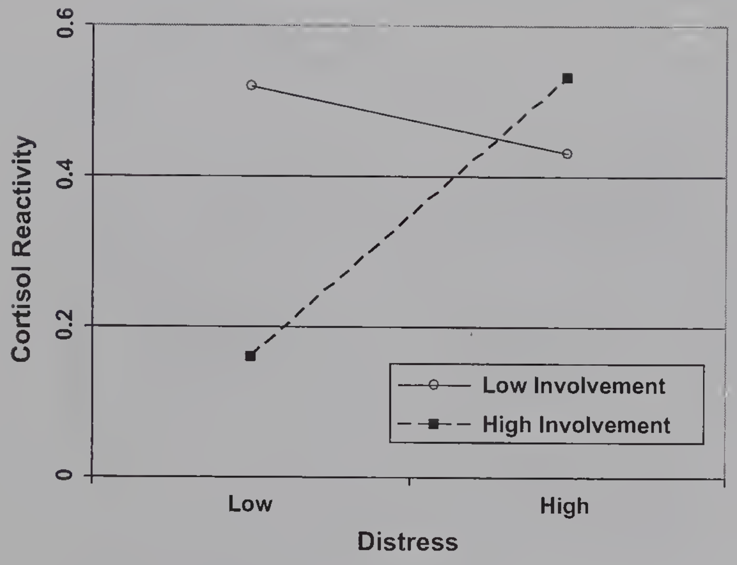

Figure 3. A graphical plot of the significant interaction between observations of children's distress and involvement responses to interparental conflict predicting their cortisol reactivity to the simulated interparental conflict.

potential interplay between children's psychological and cortisol responses to interparental conflict (Davies et al., 2006; Gunnar & Vazquez, 2006; Levine & Weiner, 1988; Spangler & Schieche, 1998). However, little is known about the concurrent interconnections between children's reactivity at these different levels of analysis. Accordingly, this study aimed to break new ground by identifying the nature of the associations between multiple dimensions of children's psychological reactivity to interparental conflict and their cortisol functioning in response to interparental conflict.

Simultaneous analysis of pathways among children's distress, hostile, and involvement responses to interparental conflict and their cortisol reactivity to interparental conflict indicated that distress was significantly and uniquely associated with higher levels of cortisol reactivity to interparental conflict. Confidence in the validity of our findings is bolstered by the considerable stability of pathways between distress responding and cortisol reactivity to conflict across several conditions. First, the specificity of associations between cortisol and distress reactivity to conflict was consistent across measures of child reactivity to conflict that varied in use of method (i.e., observation, questionnaire), informant (i.e., observer, mother), and context (i.e., laboratory, home). Thus, children's heightened cortisol reactivity to simulated interparental conflict was not only specifically associated with observational ratings of children's distress responses within the same conflict context, but it was also predicted by higher levels of maternal questionnaire reports of children's reactivity to interparental conflict in the home. Second, tests of differences in the magnitude of links between maternal reports of the three forms of psychological responding and cortisol reactivity indicated that the association between distress and cortisol reactivity was stronger than comparable paths involving child hostile and involvement responses to conflict. Third, paths between distress and cortisol reactivity were consistent even after including several demographic and child characteristics as confounding factors or moderators in the analyses.

Coherence in the results raises a central question: Why is distress reactivity to conflict uniquely associated with elevated cortisol responding to interparental conflict? Among the conceptualizations of linkages between psychological and physiological responding, the general arousal and negative affect models do not hold the precision necessary to readily explain the associations between distress and cortisol reactivity. In the general arousal model, the assumption that many forms of effortful responding to interparental conflict are coupled with greater LHPA activity would specifically suggest that distress, hostility, and involvement are relatively similar in their roles as predictors of cortisol levels. Correspondingly, the negative affect model does not distinguish between hostility and distress and assumes that negative emotionality is broad correlate of greater cortisol reactivity.

Rather, the distinctive confluence of children's heightened distress and cortisol reactivity to conflict found in the present study supports a distress specificity model and its main premise that distress is distinctly coupled with greater cortisol reactivity (Susman, Dorn, Inoff-Germain, Nottelmann, & Chrousos, 1997). Profiles characterized by elevated distress and LHPA activity in the context of interparental conflict may signify a hyperreactive threat detection system (Gunnar & Vazquez, 2006). Supporting this interpretation, EST posits that elevated distress in response to interparental conflict is a hallmark symptom of children's concerns about security (Cummings & Davies, 1996).

In further informing the distress specificity model, EST also suggests that hypersensitivity to threat may be particularly evident when distress responses to interparental conflict occur in conjunction with high levels of involvement in the conflict. In this context, attempts to intervene in adult problems by children who are distressed by interparental conflict may signify a last resort, defense strategy for preserving security when alternative solutions and resources are not accessible (Davies et al., 2006). Thus, if the blending of distress and involvement does reflect extreme considerable alarm, then distress should be a particularly potent predictor of cortisol reactivity to conflict when child involvement levels are also high. In partially supporting this interpretation, follow-up analyses of an interaction between child distress and involvement revealed that children's distress in the simulated conflict was associated with elevated cortisol reactivity to conflict only when they were also highly involved in the parental problems.

Conceptualizations of threat and challenge help to further address the mechanisms responsible for the confluence of distress and elevated cortisol reactivity. For example, one hypothesis derived from the distress specificity model is that elevations in cortisol are most likely to occur when children cannot access the resources necessary to cope with the stressor or perceive the stressor as beyond their control (Levine & Weiner, 1988; Spangler & Schieche, 1998). Applied to our findings, underlying doubts about the ability to utilize strategies necessary to preserve goals of safety and security may underlie the association between children's distress and adrenocortical reactivity (Saarni, Campos, Camras, & Witherington, 2006). Similarly, social psychological frameworks draw important distinctions between threat and challenge. Whereas the experience of threat is theorized to reflect appraisals that stressful contexts exceed coping resources available to the individual, challenges reflect perceptions that skills and resources available will be sufficient to cope with the demands of the context (Blascovich & Mendes, 2000; Dienstbier, 1989). According to these models, threat is hypothesized to be linked with elevated LHPA activity (Dienstbier, 1989; Mendes, Blascovich, Hunter, Lickel, & Jost, 2007). Integrated with the EST assumption that distress is a key indicator of concerns about safety, one interpretation is that the coupling of distress and cortisol reactivity to conflict may be rooted in the common underlying experience of threat. Although still speculative at this early stage of research, there are some bases for expecting that this response pattern may increase children's adjustment problems, particularly in the form of internalizing symptoms. For example, independent lines of research have identified children's internalizing symptoms as common sequelae of children's heightened adrenocortical reactivity to stressful events (Gunnar & Vazquez, 2006) and their elevated distress responses to interparental conflict (Davies & Cummings, 2006).

Two additional, but inconsistent, findings from our analyses .raise more speculative questions. First, maternal report of child hostility was associated with dampened cortisol reactivity to the simulated interparental conflict. Given that this pathway was only identified in one of the two main analytic models, considerable care should be taken in interpreting the results. Nevertheless, one tentative explanation derived from social psychological conceptualizations of challenge is that high levels of confidence in the ability to weather the stressfulness of interparental conflict may underlie the experience of hostile and dampened cortisol reactions to interparental conflict (e.g., Blascovich & Mendes, 2000). A related interpretation drawn from the attenuation hypothesis is that hostility may be considered dominant, bold, or callous response that may be associated with underarousal of the LHPA system in response to interparental conflict (Susman, 2006). Assuming this finding is replicated in the future, a critical step in future research is to identify the long-term implications of this response pattern. For example, within the attenuation hypothesis (Susman, 2006), the cooccurrence of hostility and dampened cortisol responses may reflect underlying disturbances in neurobiological processing of emotional and fear-relevant parameters of events that ultimately deepen and expand into broader externalizing problems. Second, the findings also indicated that maternal reports of distress were associated with lower preconflict levels of cortisol. However, a comparable path between SPAT distress and preconflict cortisol was not significant. Thus, the findings, as a whole, suggest that distress responses to interparental conflict are not consistent correlates of a broad, trait-like condition of hypercortisolism across multiple contexts. Rather, distress responses to conflict evidenced specificity in its power to predict greater cortisol reactivity to conflict.

Fully interpreting the results of our study also requires consideration of the methodological limitations. Future research on children's coping with family conflict and their cortisol functioning would benefit by increasing the rigor of psychological and physiological assessments. For example, our identification of pathways between distress reactivity and the intercept and slope parameters of cortisol functioning does not afford a thorough analysis of specificity or breadth of the adrenocortical correlates of distress responses to conflict. One important step will be to determine whether distress responding to interparental conflict is specifically associated with cortisol reactivity to interparental conflict or broader indices of cortisol reactivity to a wide array of family, interpersonal, or even more global (i.e., physical and psychosocial) stressors. Likewise, guided by conceptualizations of emotional reactivity in EST, our assessments of emotional distress were largely comprised of assessments of anxiety, fear, and general distress. As a result, our measurement battery did not permit a full analysis of associations between adrenocortical reactivity and other forms of negative emotion such as sadness. In addition, contextualizing the study of cortisol within broader profiles of functioning across multiple physiological systems may also advance psychophysiological models of coping with family conflict (Doussard-Roosevelt, Montgomery, & Porges, 2003; Gordis, Granger, Susman, & Trickett, 2006; Granger et al., 2006). For example, the modest to moderate magnitude of associations between psychological and physiological reactivity to conflict may be augmented by analyses of synchrony in functioning between the LHPA axis and the parasympathetic (e.g., Doussard-Roosevelt et al., 2003) or sympathetic (e.g., Gordis et al., 2006) nervous systems.

Future advances in identifying links between children's behavioral and physiological reactivity to conflict will also benefit from modifications in the temporal spacing of assessments. For example, the number and timing of our cortisol assessments do not permit a definitive analysis of the pattern of cortisol reactivity across stressor and recovery periods (Matthews, Gump, & Owens, 2001). Greater numbers of cortisol assessments in future research would afford flexibility in analyzing both linear and curvilinear trajectories of cortisol over time. Moreover, delineation of individual differences in recovery of cortisol may be achieved by lengthening the temporal spacing between the stressor and some of the cortisol assessments. However, relative to more common methods of assessing cortisol reactivity (e.g., difference scores between preconflict and a single postconflict measure of cortisol), our LGC analysis generated a richer characterization of cortisol reactivity through its ability to incorporate multiple assessments of cortisol that are sensitive to the direction and shape of the trajectory. Likewise, although our use of cross-sectional design is well suited to address the goal of examining the concurrent correspondence between cortisol and behavioral reactivity to conflict, use of longitudinal designs will afford tests of complementary questions about possible transactional influences among behavioral and adrenocortical reactivity over longer time periods.

Finally, although the demographic characteristics of our sample of families were highly comparable to the Northeast and Midwest regions of the United States, the findings in this study were derived from a community sample of predominantly White families. Therefore, the results of our study may not necessarily generalize to families with other racial, ethnic, or high-risk backgrounds. Nevertheless, the failure of a wide array of demographic characteristics to alter as covariates or moderators, the pathways found between children's distress and cortisol reactivity to interparental conflict provides some bases for the generalizability of the results.

In conclusion, our multimethod, multiple level of analysis study is the first foray into identifying the adrenocortical underpinnings of children's behavioral and psychological responses to interparental conflict. Consistent with the distress specificity model in the psychophysiological literature, children's distress responding to interparental conflict was consistently linked with LGC analyses of greater cortisol reactivity to interparental conflict across multiple methods (i.e., observations, questionnaires), informants (i.e., observer, mother), and contexts (i.e., laboratory, home). Moreover, the pathways were distinctive when also taking into consideration other forms of children's reactivity (i.e., hostility, involvement) to conflict and a range of sociodemographic variables as potential confounding factors. In broader accord with EST, children's security in the interparental relationship may be a central goal system organizing the confluence of distress and heightened cortisol reactivity to conflict.

Stress Regulation in Adolescents: Physiological Reactivity During the Adult Attachment Interview and Conflict Interaction

Mariëlle D. Beijersbergen, Marian J. Bakermans-Kranenburg, Marinus H. van IJzendoorn, and Femmie Juffer
Leiden University

The current study examined whether adolescents' attachment representations were associated with differences in emotion regulation during the Adult Attachment Interview (AAI; C. George, N. Kaplan, & M. Main, 1996) and during a mother–adolescent conflict interaction task (Family Interaction Task [FIT]; J. P. Allen et al., 2003). Participants were one hundred and fifty-six 14-year-old adolescents. Dismissing adolescents showed less interbeat interval (IBI) reactivity (indicating less stress) during the AAI than secure adolescents. However, during the FIT, dismissing adolescents showed more IBI reactivity. No differences in physiological reactivity were found between individuals with resolved or unresolved loss or trauma during the AAI or FIT. The results indicate that dismissing adolescents may effectively use a defensive strategy during the AAI but less so in direct conflict interaction with their attachment figure.

According to attachment theory, internal working models of attachment influence emotion regulation, both in (early) childhood and in adolescence and adulthood (Cassidy, 1994; Main, Kaplan, & Cassidy, 1985). Physiological parameters provide an excellent opportunity to test this hypothesized link (Spangler & Zimmermann, 1999), but research in this area is still scarce. Using physiological measures, the current study examined whether adolescents' working models of attachment (or attachment representations) are associated with their emotion regulation during two situations in which the attachment system is activated: during the Adult Attachment Interview (AAI; George, Kaplan, & Main, 1996; Hesse, 1999; Main, Goldwyn, & Hesse, 2003) and during a dyadic (mother–adolescent) conflict interaction task (Allen et al., 2003; Kobak, Sudler, & Gamble, 1991; Strodtbeck, 1951).

Emotion regulation patterns can be seen as part of an adaptive strategy with the goal of maintaining the relationship with the attachment figure (Cassidy, 1994). Individuals are suggested to have flexible or inflexible styles of emotion regulation, developed as the result of particular caregiving histories. Infants with secure attachment relationships as well as adults with secure attachment representations are characterized by open, flexible emotional expressions (Bretherton, 1990; Cassidy, 1994). Individuals with insecure attachment representations typically show a restricted range of emotions. Dismissing persons are suggested to systematically suppress emotions; they would mask negative affect. Evidence for the nature of this defensive strategy is still limited. Nevertheless, the first studies using physiological measures (Dozier & Kobak, 1992; Roisman, Tsai, & Chiang, 2004) suggest that dismissing individuals experience stress, although it is not displayed overtly. Preoccupied individuals, in contrast, maximize the expression of negative emotions (Cassidy, 1994; Kobak, Holland, Ferenz-Gillies, Fleming, & Gamble, 1993; Main, 1990). Even though these emotion regulation strategies may be adaptive in the relationship with the attachment figure (not being rejected or gaining attention from an unavailable caregiver, respectively), they may be maladaptive in other contexts and have negative psychological and developmental consequences (Cassidy, 1994; Cassidy & Kobak, 1988; Main, 1990).

Internal working models of attachment may also have an impact on the regulation of attention. Dismissing individuals are hypothesized to systematically exclude attachment-relevant information from consciousness (see Bowlby, 1980; Main, 1999). As a consequence, dismissing persons would usually be unable to give evidence for what they claim was a perfectly normal or very nice childhood. Preoccupied persons, on the contrary, show a strong focus on

attachment relationships and experiences (Hesse, 1999). Moreover, it has been suggested that during information processing, their attention is centered on negative emotions (Spangler & Zimmermann, 1999).

In contrast to individuals with organized attachment classifications, unresolved individuals show a momentary breakdown in their strategy (Hesse, 1999; Lyons-Ruth & Jacobvitz, 1999; Main et al., 2003). Adults are classified as unresolved when they show lapses in the monitoring of reasoning or discourse or report extreme behavioral reactions when talking about loss or other trauma (Main et al., 2003). It has been proposed that these adults may be impaired in emotion regulation when confronted with traumatic experiences (Spangler & Zimmermann, 1999).

Emotions affect physiological responses (Brownley, Hurwitz, & Schneiderman, 2004; Dawson, Schell, & Filion, 2004; Hagemann, Waldstein, & Thayer, 2003). Physiological responses are a result of the activity of the autonomic nervous system (ANS; Porges, 1995). This system consists of two subsystems: the parasympathetic nervous system (PNS) and the sympathetic nervous system (SNS). Both originate in the brainstem and influence the regulation of organs such as heart, lungs, and kidneys, as well as sweat glands, and blood vessels. The PNS is involved in growth and restorative processes in the body. The SNS quickly mobilizes existing reserves of the body when a situation requires a fight-or-flight reaction. To get insight into the activity of the ANS in situations in which emotions are elicited, measures like interbeat interval (IBI), heart rate variability (root mean of the squared successive differences [RMSSD]), and skin conductance level (SCL) have been used (Bradley, 2004).

IBI is an indicator for the time between two consecutive beats of the heart. When a person is under stressful behavior challenge (or, e.g., exercising), his or her heart rate may quicken; therefore, IBI will be shorter. RMSSD may be lower under the same challenge (Brownley et al., 2004). The level of electrodermal activity (EDA) as indexed by SCL is influenced by increases and decreases in sweat in the eccrine sweat glands (Boucsein, 1992; Dawson et al., 2004). More emotional arousal will result in higher SCL levels (Bradley, 2004). These physiological measures are suggested to be indices for stress (see Boucsein, 1992, for a review on EDA as indicator of stress; Porges, 1995) but may also be indicative of emotions like happiness or sadness, or indicative of attention, depending on the context in which these measures are used (Bradley, 2004). In adequate (stressful) contexts, they can provide a window on (negative) emotions that may or may not be expressed overtly. It is important to note that IBI, RMSSD, and SCL are differentially influenced by the SNS and PNS: IBI is influenced by both (Brownley et al., 2004), whereas RMSSD is primarily influenced by the PNS (Hagemann et al., 2003), and SCL is influenced by the SNS (Dawson et al., 2004). These measures are not interchangeable; they may show different patterns when used in the same context (e.g., Roisman et al., 2004).

In attachment research, the potential of psychophysiological parameters is increasingly used for enhancing our understanding of emotion regulation in individuals with different attachment patterns (e.g., Oosterman & Schuengel, 2007; Spangler & Grossmann, 1993; Sroufe & Waters, 1977; Zelenko et al., 2005). Only two studies, however, have examined physiological regulation during the AAI. Dozier and Kobak (1992) hypothesized that deactivation (a strategy preferred by individuals with a more dismissing representation), as contrasted with hyperactivation (more characteristic of preoccupied representations) would be related to SCL reactivity during the AAI because of its relation to behavioral inhibition (Fowles, 1980). Their findings suggested that individuals using deactivating strategies were indeed more stressed during the AAI. Roisman et al. (2004) extended this line of research by including cardiovascular reactivity (i.e., IBI reactivity) as well as skin conductance reactivity during the AAI. Convergent with their expectations, deactivation was related to SCL reactivity but not to cardiovascular reactivity (which is suggested to be indicative of behavioral activation; see Fowles, 1980). In conclusion, both studies showed an association between deactivation and increased stress during the AAI as indicated by sympathetic reactivity.

Differences in emotion regulation patterns may not only be evident during the AAI, they may also appear in other situations in which the attachment system is activated, such as in dyadic conflict interactions (Allen et al., 2003; Feeney & Cassidy, 2003). During discussions of disagreements with their parents, adolescents need to establish autonomy while also maintaining relatedness. In such conflict situations, secure individuals are supposed to be better able to balance exploration (e.g., autonomy strivings) and attachment (e.g., relatedness) than insecure individuals (Allen & Land, 1999). Focusing on physiological reactivity in adults during a discussion with their romantic partners, Roisman (2007) found that deactivation was related to SCL reactivity, whereas hyperactivation was associated with HR reactivity. Attachment security was related to less SCL reactivity during interactions with romantic partners. To our knowledge, no studies have yet investigated the link between attachment and stress reactivity during interactions between parents and their adolescent children.

The relation between attachment representation and patterns of interaction during conflict resolution has been examined before. Allen and Hauser (1996) reported that young adults' coherence of discourse during the AAI could be predicted from their mothers' promoting autonomy and relatedness 11 years earlier. Using Kobak's Q-sort (1993), Allen et al. (2003) revealed that dyadic relatedness shown in conflict interactions between mothers and 16-year-old adolescents was related to adolescent attachment security. Kobak et al. (1993) demonstrated that secure adolescents and their mothers were characterized by less dysfunctional anger and less avoidance of problem solving during conflict interactions. More dysfunctional anger as well as more maternal dominance were displayed in interactions between adolescents with deactivating strategies and their mothers.

In the current study, we examined physiological reactivity during the AAI and during an interaction task in which mothers and adolescents tried to reach consensus in an area of disagreement. It was expected that dismissing adolescents would experience more stress during the AAI than secure participants because of their hypothesized defensive strategy during the task of reflecting on early attachment experiences. In accordance with previous studies, no differences between preoccupied and secure adolescents were expected. Furthermore, unresolved individuals might show more reactivity during the questions concerning loss and (other) trauma. Regarding the conflict interaction task (Family Interaction Task [FIT]), we hypothesized that dismissing as well as preoccupied individuals would be more stressed than adolescents with secure attachment representations. No differences were expected between adolescents with resolved or unresolved states of mind because it seems unlikely that the interaction task on a disagreement would trigger memories of loss or trauma. Finally, it was expected that secure adolescents would show more autonomous relatedness during conflict interaction than insecure adolescents.

Method

Participants

Participants were one hundred and fifty-six 14-year-old internationally adopted adolescents who took part in a longitudinal study that started in infancy (Jaffari-Bimmel, Juffer, van IJzendoorn, Bakermans-Kranenburg, & Mooijaart, 2006; Juffer, Bakermans-Kranenburg, & van IJzendoorn, 2005). We report on 152 participants because in 2 cases, the AAIs of the adolescents could not be coded due to technical problems and 2 other AAIs were not classifiable because the respondents did not understand the questions due to (very) low intellectual level (IQs of 58 and 82, respectively).

Sixty-eight boys and 84 girls were involved in the current study (see Table 1). All children were adopted before the age of 6 months (M = 10.0 weeks, SD = 5.30). They came from Sri Lanka (n = 94), South Korea (n = 38), and Colombia (n = 20). The adoptive families predominantly belonged to middle class or upper middle class (Jaffari-Bimmel et al., 2006). Mean age of the adoptive mothers at the time of the birth of the children was 33.1 (SD = 3.55, N = 142) and of the adoptive fathers 35.0 (SD = 3.55, N = 141).

Procedure

The adoptive families were randomly recruited through Dutch adoption organizations and were followed from infancy to adolescence. The current study reports on the data collected at a follow-up at 14 years of age. Adolescents participated in 3.5-hr home visits together with their mothers, except for four families where the fathers participated. Results were similar when these fathers were excluded from the analyses. During the visits, the AAI was administered to the adolescents, as well as an intelligence test. The adolescents also completed questionnaires and participated in an interaction task with their mothers. One questionnaire, used as baseline for the physiological measures during the AAI, and the AAI were completed in a separate room, without the mother present. A second questionnaire, used as baseline for the physiological measures during the FIT, was completed in the presence of the mother. During the entire session, the adolescents were connected to the VU-AMS recording device (the Vrije Universiteit Ambulatory Monitoring System [AMS 36]; Groot, De Geus, & De Vries, 1998; see also Bimmel, van IJzendoorn, Bakermans-Kranenburg, Juffer, & De Geus, 2008).

Measures

AAI. The AAI (Main et al., 2003) is an hour-long, semistructured interview that assesses an individual's current state of mind with respect to attachment. In this interview, respondents were asked about their childhood experiences with their adoptive parents and how they thought they were affected by them. Other questions concerned experiences of loss and trauma. Finally, respondents were invited to describe possible changes in the relationship with their adoptive parents since childhood and the current

Note. As we only included adolescents who experienced loss or trauma in the resolved and unresolved categories, the total *n* for this subgroup is 133. AAI = Adult Attachment Interview.
[a] Range *n* = 54–57. [b] Range *n* = 61–62. [c] Range *n* = 30–33. [d] Range *n* = 108–110. [e] Range *n* = 22–23. [f] Range *N* = 147–152. [g] Number of words used during responses to AAI questions 6–11, except for 9a, which is about abuse.

relationship with them. On basis of verbatim transcripts of the AAI, the adolescents were judged as having a secure (F), dismissing (Ds), or preoccupied (E) attachment representation. The discourse of secure individuals is coherent. They are able to freely value their experiences and yet stay objective regardless of the nature of their experiences. Individuals with an insecure attachment representation significantly violate Grice's (1975) criteria for coherence. Dismissing individuals typically idealize their parents and claim lack of memory for their childhood. In rare cases, they derogate their attachment experiences. Individuals with a preoccupied state of mind are still confused and overwhelmed by their childhood experiences. They are angry toward their parents or their discourse is characterized by vague speech (Main et al., 2003). On top of their main classification, individuals may be classified as unresolved-disorganized (U) when they show lapses in the monitoring of reasoning or discourse in reaction to loss or other traumatic events (Main et al., 2003).

Previous studies provided preliminary evidence for the validity of the AAI in adolescent samples. For example, continuity of attachment from infants' Strange Situation classifications (Ainsworth, Blehar, Waters, & Wall, 1978) to adolescents' AAI classifications has been reported (e.g., Hamilton, 2000; Main, Hesse, & Kaplan, 2005). In addition, adolescent attachment representations as assessed with the AAI were associated with several developmental outcomes in the predicted way (e.g., Adam, Sheldon-Keller, & West, 1996; Mayseless & Scharf, 2007). Although these studies usually involved adolescents with a mean age of 16 years or older, one study reported considerable stability of the AAI classifications when 10-year-olds were reassessed 4 years later (Ammaniti, van IJzendoorn, Speranza, & Tambelli, 2000). In addition, using Kobak's Q-sort (1993), Allen and colleagues. (Allen, Porter, McFarland, Boykin-McElhaney, & Marsh, 2007; Allen, Porter, McFarland, Marsh, & Boykin-McElhaney, 2005) found associations between 14-year-olds' attachment representations and mother–adolescent and father–adolescent interactions 1 year earlier. The validity of the AAI in (early) adolescence thus looks promising.

The AAIs were coded by the first author. For interrater reliability, 18 randomly selected interviews were also coded by the second author. Interrater agreement was 78% ($\kappa = .64$) for three-way classifications (secure, dismissing, and preoccupied) and 83% ($\kappa = .77$) for four-way classifications (secure, dismissing, preoccupied, and unresolved). Disagreements between coders were resolved by discussion. Intraclass correlation for the overall unresolved score was $r = .89$. Finally, a continuous dismissing score was derived by using the maximum score of an individual on the following scales: idealization of mother, idealization of father, derogation of mother, derogation of father, and overall derogation of attachment. Intraclass correlation for the dismissing score was $r = .71$.

Of the 152 adopted adolescents, 57 (37.5%) were secure, 62 (40.8%) dismissing, and 33 (21.7%) preoccupied. Taking the unresolved category into account, the distribution was: 50 (32.9%) secure, 57 (37.5%) dismissing, 19 (12.5%) preoccupied, and 26 (17.1%) unresolved. The distribution of classifications in our sample differed significantly from the normative distribution in nonclinical adolescent samples (van IJzendoorn & Bakermans-Kranenburg, 2008) for the three-way distribution, $\chi^2(2, N = 152) = 30.74, p < .01$, as well as for the four-way distribution, $\chi^2(3, N = 152) = 15.36, p < .01$. In the current sample, the insecure categories were overrepresented.

In order to test the validity of the AAI in the present sample, we investigated whether emotional investment in others versus self was related to adolescents' AAI classifications. Because dismissing individuals tend to emphasize their independence and dismiss the importance of attachment relationships (Hesse, 1999), they were expected to emotionally invest less in others than nondismissing individuals who value attachment relationships (secure individuals) or feel emotionally very dependent on others (preoccupied individuals; see Mikulincer & Shaver, 2007). Our findings confirmed this hypothesis (Beijersbergen, van IJzendoorn, Bakermans-Kranenburg, & Juffer, 2007), providing additional support for the validity of the AAI when used with adolescents.

Attachment classification was not associated with gender, country of birth, socioeconomic status (SES), health condition or age at adoptive placement, age at time of assessment, number of sports, smoking, or intelligence. A significant association was found between number of words used during the AAI and attachment classification, with preoccupied individuals using the most words, whereas dismissing individuals gave the shortest answers, $F(2, 149) = 33.85, p < .01$.

FIT. Using a revealed differences task (Strodtbeck, 1951), we investigated the patterns of interaction between adolescents and their mothers (Allen et al., 2003; Kobak et al., 1991). Mothers and adolescents were asked to discuss and try to reach consensus on an issue on which they disagreed during 10 min. The discussion started after they listened to a tape that had been recorded in absence of the mother, on which the adolescent stated his or her opinion about the disagreement, as well as the opinion the adolescent thought the mother had.

The interactions were coded with the autonomy and relatedness coding system of Allen and colleagues (Allen et al., 1994). Adolescents received scores ranging from 0 to 4 on four scales (derived from nine subscales): (a) *exhibiting autonomy*, states reasons clearly for disagreeing, confidence in stating thoughts and opinions; (b) *inhibiting autonomy*, recanting a position, overpersonalizing, pressures to agree; (c) *exhibiting relatedness*, validates/agrees/positively reacts to other person, engaged interaction; and (d) *inhibiting relatedness*, distracting/ignoring, hostile/devaluing statements. The subscale *recanting a position* was excluded from the inhibiting autonomy scale because it was not associated with the other two subscales as a consequence of lack of variance. Because the inhibiting autonomy and inhibiting relatedness scales were strongly correlated ($r = .72$, $p < .01$), they were combined into one scale, *inhibiting autonomy relatedness*. The scales concerning exhibiting autonomy and exhibiting relatedness were not combined because the correlation between these scales was modest ($r = .29, p < .01$). The discussions were coded by two different coders who were unaware of other characteristics of the dyads and who were both trained by an expert who received training from Dr. J. P. Allen. Mean intercoder reliability between the expert and the two coders was .79 (range = .68 – .92, $n = 30$). Internal consistency of the three major scales used in the analyses was adequate (exhibiting autonomy $\alpha = .82$, exhibiting relatedness $\alpha = .60$, and inhibiting autonomy relatedness $\alpha = .82$).

Table 2 presents means and standard deviations of the autonomy-relatedness scales. Scale scores were missing for 1 participant because no parent was present during the session. The autonomy-relatedness scales for one other adolescent could not be scored because of technical problems with the recording.

Physiological measures. The VU-AMS recording device (Groot et al., 1998) was used to measure IBI, RMSSD (an index for heart rate variability), and galvanic SCL. These measures were selected to replicate (IBI and SCL) and extend (RMSSD) prior work by Dozier and Kobak (1992) and Roisman et al. (2004). We assume that IBI reactivity, RMSSD reactivity, and SCL reactivity scores of the adolescents are indices of stress because these measures were used during two potentially stressful tasks.

Table 2
Scores on Autonomy-Relatedness Scales of the Family Interaction Task (FIT) per Attachment Classification

	Secure ($n = 56$)[a] M (SD)	Dismissing ($n = 61$)[a] M (SD)	Preoccupied ($n = 33$) M (SD)	Resolved ($n = 108$)[b] M (SD)	Unresolved ($n = 23$) M (SD)	Total ($N = 150$)[b] M (SD)
Exhibiting autonomy	2.39 (0.69)	2.00 (0.75)[c]	2.35 (0.84)	2.26 (0.78)	2.17 (0.71)	2.22 (0.76)
Exhibiting relatedness	1.65 (0.59)	1.64 (0.60)	1.67 (0.62)	1.61 (0.57)	1.79 (0.66)	1.65 (0.60)
Undermining autonomy relatedness	1.07 (0.78)	0.86 (0.72)	1.03 (0.74)	0.94 (0.73)	1.10 (0.82)	0.98 (0.75)

Note. As we only included adolescents who experienced loss or trauma in the resolved and unresolved categories, the total N for this subgroup is 133.
[a] FIT is missing for one participant in this group. [b] FIT is missing for two participants in this group. [c] *Mean difference dismissing – secure* = 0.39, *SE* = 0.14, $p < .05$.

Three disposable electrocardiogram electrodes were placed on the adolescent's chest: The first was placed at the jugular notch of the sternum, between the collarbones; the second was placed below the left breast, 4 cm (1.5 inch) under the nipple, between two ribs; the last electrode was placed at the right side of the chest, between the lower two ribs. The SCL electrodes were placed on the thenar and hypothenar eminences of the palms of the hands. The VU-AMS device continuously recorded IBI. RMSSD was calculated based on the raw IBI data and was sampled every 10 s. SCL was sampled every 500 ms. The quality of the signal and attachment of the electrodes were checked by online monitoring of the physiological data. The VU-AMS device failed to record physiological data during one home visit. SCL recordings were unreliable for 1 participant, and another participant had unreliable physiological recordings during the AAI. For one adolescent, the equipment failed to record physiology after the introduction of the FIT. The corresponding data were excluded from the analyses.

Physiological values during the answers to the following AAI questions were used in the analyses (George et al., 1996): (6) When you were upset when you were little, what did you do, what would happen? Can you think of specific incidents? Physically hurt? Ill? (7) Could you describe your first separation from your parents? (8) Did you ever feel rejected as a child? What did you do? Do you think your parents realized they were rejecting you? (8a) Were you ever frightened or worried as a child? (9) Were your parents ever threatening with you—maybe for discipline or jokingly? (9a) Some people have memories of some kind of abuse. Did that ever happen to you, or in your family? (10) How do you think your overall experiences have affected your adult personality? (10a) Are there any aspects to your early experiences that you feel were a setback in your development? (11) Why do you think your parents behaved as they did, during your childhood? (13) Did you experience the loss of a parent or other close loved one? (14) Have you had any other experiences which you would regard as potentially traumatic? These questions were selected because we expected that they would show the largest differences in physiological reactivity between the organized secure and insecure attachment strategies (e.g., questions 6–9 and 10–11) or between persons with an resolved or unresolved state of mind (e.g., questions 9a, 13, and 14). The last 3 min of the episode in which the adolescents were alone completing a questionnaire was used as baseline for the AAI. Because 7 adolescents did not fill in the questionnaire, they could not be included in the analyses.

During the FIT, physiological values were recorded for 4.5 min starting from the moment the dyad began the discussion. After 4.5 min, a number of mothers and adolescents drifted away from the original task and began a conversation about nonproblem issues, for example, about the day at school. The last 3 min of the episode in which the adolescents completed a questionnaire in the presence of the mother was used as baseline for the FIT. Two adolescents did not fill in this questionnaire and were therefore excluded from the analyses.

Implausible physiological values were deleted (De Geus, 1996; Groot et al., 1998). Physiological reactivity was calculated per AAI question for IBI, RMSSD, and SCL by subtracting means of the AAI baselines from the means during the selected AAI questions. Physiological reactivity during the FIT was computed by subtracting the FIT baseline from the means during the FIT. More reactivity, and thus more stress, is indicated by higher SCL, lower IBI, and lower RMSSD difference scores. Covariates (as indicated under the AAI subsection) were only included if they were associated with the dependent as well as the independent variables. Following Keppel and Wickens's (2004) recommendation concerning extreme scores, we included outliers in the analyses. Results remained similar when outliers were changed into the next most extreme scores (Tabachnick & Fidell, 2001).

Intelligence. Intelligence was included because it may affect heart rate: Higher IQ has been associated with heart rate deceleration (Lewis & Wilson, 1970; but see Farrington, 1997, for an exception). The adolescents completed the abbreviated Groningen Intelligence Test (Luteijn & Van der Ploeg, 1983). The following three subsets were included: cipher, enumerate words, and word matrices. Mean IQ score was 100.6 (*SD* = 13.09).

Physical condition and smoking. Physical health and smoking influence heart rate (De Geus, Boomsma, & Snieder, 2003; Farrington, 1997; Vander, Sherman, & Luciano, 2001). We therefore asked participants in which sports they had been active in the previous year. Participants were also asked to rate on a 5-point scale how much they smoked (1 = *never* to 5 = *often*).

Health condition at placement. Health condition at adoptive placement was used as an index for the health condition of the infant from birth to placement in the family (Stams, Juffer, & van IJzendoorn, 2002). Information for this index was gathered in the first interview with the parents, which was conducted when the infants were 5 months old. Health condition at placement was calculated by the standardized summation of (a) birth weight, (b) incidence of prematurity, and (c) health problems at placement (reversely coded). Higher scores represent better health condition at placement.

Socioeconomic status. SES of the adoptive families was assessed when the children were 7 years old, combining the educational and vocational background of both parents (for more details, see Stams et al., 2002). Scores for SES correspond to socioeconomic strata as follows: 3–9 lower class, 9–12 middle class, and 12–16 upper class. Adoptive families had a mean SES of 10.0 (*SD* = 2.65).

Data Analysis

First, analyses were conducted for physiological reactivity during the AAI. Linear mixed models were run with attachment representation, question, and the interaction between question and attachment representation as fixed effects. We also tested whether subject should be included as a random effect and which covariance structure should be used for the error term. For each physiological measure, the best fitting models were selected using Akaike's information criterion and log likelihood (Fitzmaurice, Laird, & Ware, 2004). Post hoc tests were conducted to test whether secure individuals significantly differed from dismissing and preoccupied individuals with regard to physiological reactivity during the AAI. Finally, we calculated correlations between the dismissing score and physiological reactivity.

For the analyses concerning unresolved loss, we selected the participants who did report loss or trauma during the AAI (n = 133). Because all adolescents were adopted before the age of 6 months and they were asked about their own memories concerning loss or trauma, all reported experiences concerned postadoption loss or trauma. Linear mixed model analyses were conducted with the classification unresolved with respect to loss or trauma, question, and the interaction between question and unresolved attachment as fixed effects. Correlations were calculated between the overall unresolved score (for either loss or other trauma) and physiological reactivity.

Next, physiological reactivity during the FIT was examined. We conducted the same analyses (three-way classifications and resolved vs. unresolved classifications; dismissing score and unresolved score) for the AAI data. Finally, reactivity during the selected AAI questions was averaged to compare reactivity during AAI and FIT. We tested whether one task caused more physiological reactivity than the other, whether persons with different attachment classifications differed in reactivity during both tasks, and whether there was an interaction effect between task and attachment.

Results

Preliminary Analyses

With a multivariate analysis of variance, we tested for significant differences in autonomy relatedness between adolescents with divergent attachment classifications. The overall effect was not significant, $F(6, 290) = 1.60, p = .15$. However, because we had a priori hypotheses regarding the different types of adolescents' interactive behaviors and the sphericity assumption held, more powerful focused univariate analyses were also conducted (Keppel & Wickens, 2004). A significant effect was found for exhibiting autonomy, $F(2, 147) = 4.56, p < .05$. Secure adolescents ($EM = 2.39$, $SE = 0.10$) had higher scores on this scale than dismissing adolescents ($EM = 2.00, SE = 0.10$). Exhibiting autonomy during the FIT was also negatively associated with the AAI dismissing scale ($r = -.18, p < .05$). No association was found between the dismissing scale and showing relatedness ($r = -.03, p = .69$) or inhibiting autonomy relatedness ($r = -.03, p = .68$).

Unresolved and not-unresolved adolescents showed no differences in autonomy-relatedness scores, $F(3, 127) = 2.42$, $p = .07$. Moreover, none of the correlations between the autonomy-relatedness scales and the unresolved score in the group of adolescents who experienced loss or trauma ($n = 131$) was significant (exhibiting autonomy $r = .06$, $p = .49$; exhibiting relatedness $r = .17$, $p = .06$; inhibiting autonomy relatedness $r = .16$, $p = .08$).

Physiological Reactivity During the AAI

Means and standard deviations of the raw physiological data during baseline as well as during the AAI questions are presented in Table 3. Neither secure, dismissing, and preoccupied participants nor resolved and unresolved participants had significantly different baselines for IBI, RMSSD, or SCL.

Associations between physiological reactivity during the AAI and background variables. A significant relation was found between IBI reactivity and age at time of the assessment. Furthermore, RMSSD reactivity was related to smoking and gender. SCL reactivity was associated with the following variables: age at adoptive placement, age at time of assessment, country of origin, and number of words used during the AAI. A table presenting all statistics concerning the relations between physiological reactivity and background variables for the total group as well as for the group who experienced loss or trauma is available upon request.

Table 3

Physiological Assessments: Raw Values for the Baseline and AAI Questions

	IBI[a]		RMSSD[b]		SCL[c]	
Question	*M*	*SD*	*M*	*SD*	*M*	*SD*
Baseline	779.85	92.73	54.33	26.72	11.26	7.96
Upset	761.31	94.37	48.76	23.54	11.54	7.95
Separation	761.68	92.78	49.75	24.18	11.52	7.65
Rejection	779.64	99.11	50.69	25.77	11.39	7.44
Frightened	764.80	96.55	50.69	26.44	11.58	7.69
Threatened	776.75	101.40	50.74	26.60	11.62	7.55
Effects	770.32	95.10	50.19	23.93	11.73	7.50
Setback	780.90	105.11	52.98	28.35	11.54	7.47
Why behaved	769.39	96.14	51.24	26.41	11.65	7.49
Abuse	786.45	105.33	52.14	28.26	11.66	7.45
Loss	770.83	98.49	52.39	27.58	11.67	6.97
Other trauma	774.44	98.04	52.82	28.77	11.79	7.26

Note. IBI = interbeat interval; RMSSD = root mean of the squared successive differences; SCL = skin conductance level.
[a] $N = 150$, except for baseline IBI ($N = 141$). [b] N ranges between 147 and 149, except for baseline RMSSD ($N = 139$). [c] $N = 149$, except for baseline SCL ($N = 142$).

For the adolescents who experienced loss or other trauma, we found a relation between IBI reactivity and intelligence. In this subgroup, SCL reactivity was associated with age at time of assessment, number of sports, and number of words used during the AAI. Because number of words used during the AAI was related to SCL reactivity as well as to the three-way attachment classification, we used this variable as a covariate in all pertinent analyses.

Differences between secure, dismissing, and preoccupied adolescents. A linear mixed model for IBI reactivity with a diagonal covariance structure and subject included as a random effect showed that attachment representation, question, and the interaction between question and attachment representation were all significant, $F(2, 140) = 3.37$, $p < .05$; $F(7, 235) = 14.09$, $p < .01$; and $F(14, 235) = 1.77$, $p < .05$, respectively. Adolescents appeared to be most reactive during the questions related to being upset and being separated (respectively, $M = 17.86$, $SD = 51.64$; $M = 18.12$, $SD = 50.79$). In contrast, they showed least reactivity during the setback question ($M = -2.17$, $SD = 53.97$). Post hoc tests revealed that dismissing participants showed less IBI reactivity than secure ones (M *difference* $= -22.60$, $SE = 8.91$, $df = 140$, $p < .05$), indicating that they were less stressed than secure adolescents (see Figure 1). No differences were found between secure and preoccupied adolescents (M *difference* $= -6.29$, $SE = 10.84$, $df = 140$, $p = .99$). Finally, the interaction between attachment and

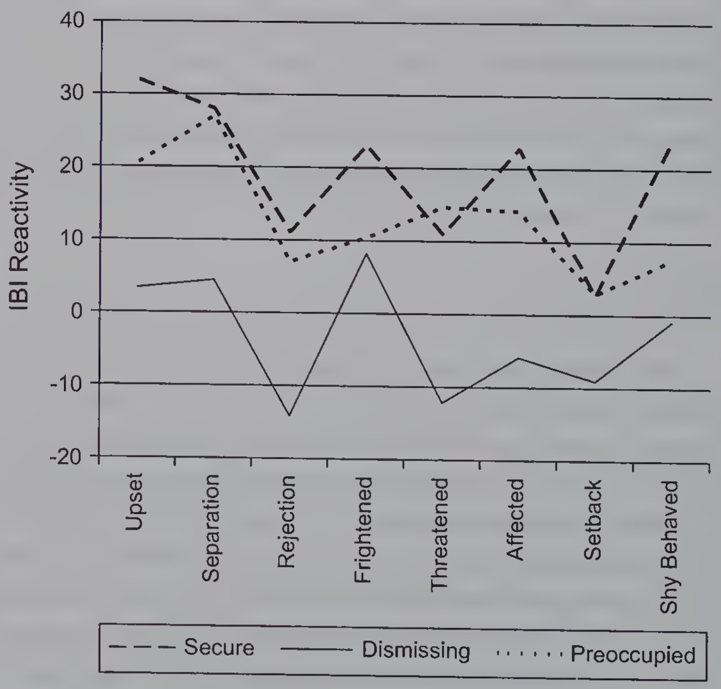

Figure 1. Interbeat interval reactivity of secure, dismissing, and preoccupied adolescents during the Adult Attachment Interview.

question revealed that for the questions on separation, $t(201) = 2.27$, $p < .05$, and threat, $t(218) = 2.24$, $p < .05$, preoccupied adolescents showed an increase in IBI reactivity, whereas secure individuals displayed a decrease in IBI reactivity.

Adolescents with secure, dismissing, or preoccupied classifications did not differ significantly from each other on RMSSD reactivity, $F(2, 137) = 0.81$, $p = .45$, or on SCL reactivity, $F(2, 141) = 1.35$, $p = .26$. Participants displayed more SCL reactivity during the question how they were affected by their childhood than during the question on rejection (*M difference* = 0.36, *SE* = 0.11, *df* = 585, $p < .05$). When the outliers were changed into the next most extreme scores, the adolescents also showed more SCL reactivity during the frightening and threatening questions than during the rejection question (*M difference* = 0.23, *SE* = 0.07, *df* = 912, $p < .05$; *M difference* = 0.27, *SE* = 0.09, *df* = 905, $p < .05$). Because the results of the analyses with SCL reactivity did not change whether or not number of words used during the AAI was included, only the statistics of the analyses without number of words as covariate are presented.

Dismissing score. Controlling for background variables that were associated with the physiological measures and the dismissing score, we found that higher scores on the dismissing scale were associated with lower IBI reactivity during the questions concerning being upset and when asked for effects of childhood experiences ($r = -.18$, $p < .05$; $r = -.22$, $p < .05$, respectively). A trend was found for the relation between the dismissing score and the question about separations ($r = -.16$, $p = .06$). When the outliers were changed into the next most extreme scores, the correlation between the dismissing scale and the IBI reactivity during the question about rejection was also significant ($r = -.17$, $p < .05$). Adolescents with higher dismissing scores tended to show less reactivity during these questions. RMSSD and SCL reactivity were not related to the dismissing scale during any of the selected AAI questions (RMSSD separate scores for gender: range $r = -.23$ to .19, $p = ns$; SCL range $r = -.04$ to $-.08$, $p = ns$).

Do adolescents with and without unresolved attachment classifications differ in physiological reactivity during the AAI? The results for SCL reactivity remained the same when number of words was included in the analysis as a covariate, we therefore only report statistics of the linear mixed model for SCL reactivity without number of words. The linear mixed models for IBI, RMSSD, and SCL had a diagonal covariance structure and included subject as a random effect. Question was a significant predictor for IBI, $F(2, 158) = 9.69$, $p < .001$: All adolescents showed more IBI reactivity ($M = 12.45$, $SD = 49.09$) during the loss question, indicating that this question was more stressful than the questions concerning abuse ($M = 6.32$, $SD = 53.69$) and other trauma ($M = 9.90$, $SD = 53.39$). In none of the tests, unresolved attachment with respect to loss or trauma was a significant predictor of physiological reactivity, IBI, $F(1, 127) = 0.42$, $p = .52$; RMSSD, $F(1, 120) = 0.42$, $p = .52$; and SCL, $F(1, 123) = 0.03$, $p = .86$. Physiological reactivity was neither related to the unresolved loss score.

Physiological Reactivity During the FIT

In order to keep the analyses concise and focused, we decided to follow through only on IBI reactivity during the FIT because adolescents with different attachment representations differed in IBI reactivity during the AAI. Mean IBI baseline value was 794.11 ($SD = 110.46$), whereas mean IBI value during the FIT was 775.63 ($SD = 104.82$).

Secure, dismissing, and preoccupied adolescents. Means of IBI reactivity for the three attachment classifications were 9.43 ($SD = 46.81$) for secure adolescents, 30.90 ($SD = 58.33$) for dismissing adolescents, and 9.87 ($SD = 52.00$) for preoccupied adolescents. The contrast for secure versus dismissing adolescents showed a significant difference (difference = 21.48, $SE = 9.84$, $p < .05$): Dismissing adolescents showed more reactivity, which suggests they felt more stressed than secure adolescents during the FIT. The dismissing scale was significantly associated with IBI reactivity ($r = .18$, $p < .05$).

IBI reactivity during the FIT and unresolved loss/trauma. No significant differences were found for IBI reactivity between adolescents with or without an unresolved attachment classification, $F(1, 127) = 0.87$, $p = .35$, and the unresolved score was not correlated to IBI reactivity during the FIT ($r = -.03$, $p = .76$, $n = 129$).

IBI Reactivity During the AAI and the FIT

A linear mixed model was run with IBI reactivity as dependent variable and task and attachment classification as independent variables. There was no significant main effect for task, $F(1, 280) = 1.33$, $p = .25$, nor for attachment, $F(2, 280) = .07$, $p = .93$. The interaction between task and attachment was significant, $F(2, 280) = 6.18$, $p < .01$. As can be seen in Figure 2, in comparison with the secure adolescents, dismissing adolescents showed more IBI reactivity during the FIT, whereas they displayed less reactivity during the AAI, $t(280) = -3.34$, $p < .01$.

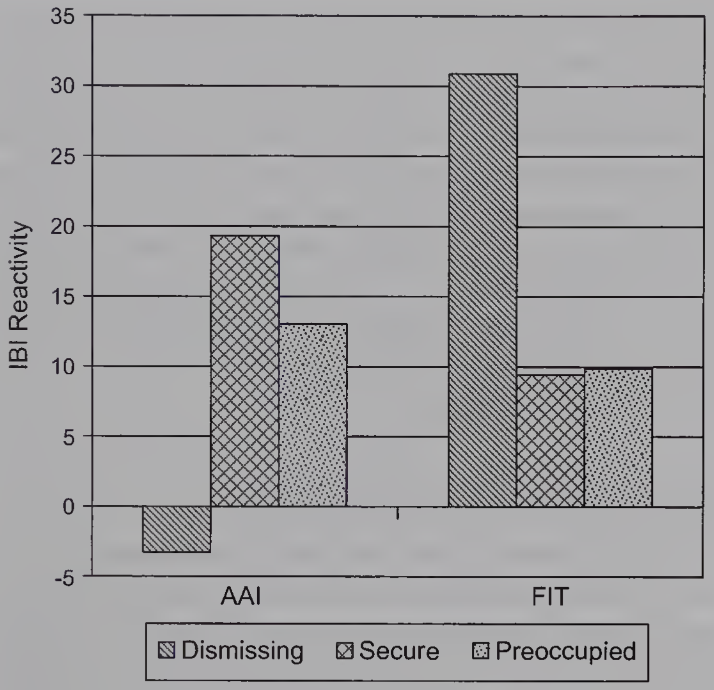

Figure 2. Differences in interbeat interval reactivity during the Adult Attachment Interview (AAI) and during the Family Interaction Task. (FIT).

Discussion

The current study investigated whether attachment classification was related to physiological reactivity during the AAI (Main et al., 2003) and during a dyadic interaction task (FIT; Allen et al., 2003; Kobak et al., 1991; Strodtbeck, 1951). IBI reactivity suggested that dismissing participants were less stressed during the AAI than secure adolescents. However, during the conflict interaction task, involving a discussion with their mother on an issue on which they disagreed, dismissing adolescents seemed to be more stressed. Furthermore, during the AAI questions about separation and threat, preoccupied individuals showed elevated IBI reactivity, whereas secure individuals displayed decreases in reactivity. We found no differences in physiological reactivity between adolescents with a resolved or unresolved state of mind during the AAI or during the FIT. In addition, there were no differences in IBI reactivity between the AAI and the FIT, and there was no overall effect for attachment. However, a significant interaction effect indicated that in comparison with secure adolescents, dismissing adolescents were more stressed during the FIT and less stressed during the AAI.

Our study extends previous research with a broader spectrum of physiological measures during the AAI. Moreover, we examined not only associations with secure, dismissing, and preoccupied attachment classifications but also tested whether individuals with and without unresolved loss showed different physiological reactivity during the pertinent AAI questions on loss and (other) trauma. We used Main et al.'s (2003) classification system instead of Kobak's Q-sort (1993) as was done in previous studies. Furthermore, the present study was conducted in the home; whereas prior studies conducted the AAI in a laboratory setting, that setting may be more stressful than the home. In addition, according to our knowledge, no other studies have yet focused on physiological reactivity shown by persons with different attachment representations during a mother–adolescent conflict interaction task. Finally, our sample consisted of adolescents. The present findings thus extend previous physiological investigations. Nevertheless, further studies are necessary to draw more definite conclusions regarding physiological reactivity in attachment-relevant situations, in adolescents as well as in adults.

Dismissing adolescents did not seem to experience more stress during the AAI, whereas they did appear to be more stressed than secure adolescents during the FIT as indicated by IBI reactivity. Both tasks place different demands on the participants. During the AAI, participants are asked to produce their childhood memories and reflect on them (Hesse, 1999). Our findings suggest that dismissing adolescents are less open to the challenge of the AAI than secure adolescents and are able to cope with the interview in a somewhat superficial manner. They might therefore display less IBI reactivity during the AAI, but it seems impossible to be uninvolved and detached during a direct interaction task with their mother with the goal of reaching consensus in an area of disagreement. We thus propose that the defensive strategy of dismissing adolescents might be effective during the AAI even at an early stage of information processing, and that they are less open to seriously address these intimate questions compared to secure adolescents. This hypothesis has been suggested before. In a study using the Stroop test (Zeijlmans Van Emmichoven, van IJzendoorn, De Ruiter, & Brosschot, 2003), persons with a secure attachment representation showed slower response latencies than insecure persons. Moreover, clinical subjects with a secure attachment representation had the largest response times to threat words. The authors therefore hypothesized that secure individuals may be more open to this type of threatening information that is carefully processed, whereas dismissing individuals exclude this unbalancing information at an early stage.

It should be noted that this hypothesis of excluding attachment-related memories and experiences at an early stage of information processing may pertain to adolescents only, as prior work on adults showed a different picture. Adolescents are different from adults in that they did not have had much time to work through their attachment experiences and are in the process of becoming less dependent on their parents (Allen & Land, 1999; van IJzendoorn & Bakermans-Kranenburg, 2008). Adolescents also differ from adults in that their brain is not yet fully developed (see for a review, Blakemore & Choudhury, 2006). Maturation of the frontal cortex continues into adolescence. Magnetic resonance imaging studies have shown changes in white and gray matter during adolescence, which may be indicative of increased axonal myelination and synapse proliferation. These changes may account for the lower capacity of adolescents to control and coordinate their thoughts and behavior (executive function, including selective attention, decision making, voluntary response inhibition, and working memory) as compared to adults. Adolescents may thus show a different pattern of associations between AAI representations and (physiological) responses because of their transitional life stage (becoming less dependent on their parents) and their less developed cognitive functioning (less mature frontal cortex).

In contrast to their lower physiological reactivity during the AAI, dismissing adolescents appeared to be more stressed than secure adolescents during the FIT. When the dismissing adolescents are in direct interaction with their mother, they may have less opportunity to effectively use defensive processes, and they may thus experience more stress than secure adolescents. In the FIT, the stakes may be felt to be higher because the discussion pertains to present real-life conflict issues, and the mother may play a more demanding or provocative role than an unknown interviewer who is not able to check the validity of any response. This result converges with a study of Roisman (2007) in which deactivation was associated with SCL reactivity during the discussion of a disagreement with the participant's romantic partner.

Differences between dismissing and secure adolescents during the FIT may also be due to their mothers' contribution during this task. Mothers' interactions during the discussion vary across dyads and may be dependent on the adolescent's behavior. The interactive behavior of mothers of dismissing adolescents might be more stress evoking than that of mothers of their secure counterparts. In fact, during the FIT, both dismissing adolescents and their potentially dismissing or insensitive mothers contribute to the conflict interaction which might exacerbate the tensions in the relationship compared to stress felt during the unilateral AAI narrative.

Preoccupied adolescents differed from adolescents with a secure attachment representation only in their response to the questions on separation and threat during the AAI. During the FIT they did not differ in reactivity from secure adolescents. The strategy of these individuals is to maximize attention to attachment relationships and experiences (Hesse, 1999). The AAI and the FIT thus seem not to challenge preoccupied adolescents like they do dismissing individuals, which fits nicely with the idea that preoccupied persons are used to talk about relationships and emotional experiences. In addition, the FIT provides preoccupied individuals with the undivided attention of their attachment figure. During the AAI questions regarding separation and threat, these individuals may be especially triggered to recall anxious experiences and as a consequence show elevated IBI reactivity. Roisman (2007) showed that hyperactivation was associated with more heart rate reactivity during a discussion between romantic partners. However, relationships between adolescents and their parents and between romantic partners have different characteristics. Romantic partners may decide to end the relationship which raises intense feelings of anxiety in preoccupied individuals, whereas even preoccupied adolescents may always feel the strong bond with their parents—whether or not this bond is (in)secure.

We found differences in cardiac reactivity as opposed to SCL reactivity. Because no difference in RMSSD reactivity (which is an indicator of parasympathetic activation) was found between adolescents with a dismissing or secure attachment representation, we tentatively speculate that differences in IBI reactivity may be mainly due to differences in sympathetic activation (see Roisman, 2007). Activation of the sympathetic branch has been associated with deactivation of attachment before (e.g., Dozier & Kobak, 1992; Roisman, 2007; Roisman et al., 2004). This seems to be in contrast with the result that SCL reactivity was not associated with adolescent attachment; however, the lack of findings for SCL may be (partly) a consequence of the various ethnicities represented in the current sample. SCL is suggested to be influenced by a person's ethnicity; for example, White participants tend to have higher SCL levels than Black participants (Boucsein, 1992). As our sample consisted of adolescents with different ethnic backgrounds, this may have been a problem for our SCL recordings. Although we controlled for possible associations between SCL and country of origin, a more specific measure for ethnicity may be needed as even adolescents from the same country may vary widely in skin color.

We found no differences in physiological reactivity between resolved and unresolved adolescents. This might be due to the way we measured physiological reactivity. We only focused on reactivity during the loss, abuse, and trauma questions but experiences of loss and trauma may also be discussed in other parts of the AAI. Moreover, the breakdown in strategy by which unresolved loss is characterized is usually very brief (Hesse, 1999; Hesse & Main, 2000), consequently physiological changes may also have been momentary rather than during the entire response to these questions. Future research should try and connect the moment of breakdown in speech during the AAI with the recordings of physiological reactivity.

Although the adolescents in our sample were adopted, they may not be too different from other adolescents. They were adopted in infancy, at a very early age (before 6 months), and were not selected on special needs. Their mean IQ score was not different from the norm for 14- to 15-year-olds, $t(150) = 0.57$, $p = .57$. Moreover, although they had less optimal scores for inhibiting autonomy relatedness compared to a high school sample (Allen & Hauser, 1996), they exhibited more optimal autonomy behaviors compared to an academic low-risk group (Boykin-McElhaney & Allen, 2001). The adoptive status of the adolescents may, however, (partly) account for the relatively high percentage of insecure attachment representations in our sample. The adopted adolescents experienced the loss of their birth parents and possibly other attachment figures, even when they do not explicitly remember them. In addition, their adoptive status may be an issue in particular during adolescence because of the process of identity formation in this stage of life (Brodzinsky, Schechter, & Henig 1992; but see Juffer & van IJzendoorn, 2007).

A limitation of the current study may be that during the baseline periods, adolescents completed a questionnaire, whereas they answered interview questions or were involved in a discussion during the two target tasks. Speaking versus completing a questionnaire may differentially influence physiological activity (e.g., Berntson et al., 1997). However, we were not so much interested in the comparison of physiological response during baseline and these two tests. Our focus pertained to physiological differences in reactivity between adolescents with different attachment representations. We controlled for number of words when necessary, but the findings remained the same.

In sum, the current study is the first to investigate physiological reactivity in adopted adolescents during the AAI as well as during a dyadic conflict interaction task. We propose that dismissing adolescents appear to be able to effectively use their defensive strategy during the AAI as they seem to be less stressed than adolescents with a secure attachment representation, but they appear to experience more stress than secure adolescents in direct interaction with their mothers around a conflict issue. Attachment representations thus play an important role in emotion regulation in attachment-relevant conflict situations, also during adolescence.

Effects of Aggression on Achievement: Does Conflict With the Teacher Make It Worse?

Deborah Stipek and Sarah Miles
Stanford University

This longitudinal study examined different explanations for negative associations between aggression and academic achievement using data collected from 403 children from low-income families followed from kindergarten or first grade (ages 6 and 7 years) through fifth grade (ages 10 – 11 years). Most results of growth curve analyses examining change over time and path analyses examining associations among the variables within grades were consistent with the hypothesis that the effect of aggression on achievement was partially mediated by the conflictual relationships relatively more aggressive children tended to develop with their teachers and concomitant reductions in engagement in academic tasks. The evidence suggested, however, that the relationship between aggression and achievement is complex and reciprocal. Gender differences were also observed.

Countless studies have found associations between children's social behavior and their academic performance (for an illustration of a study that did not find these associations, see Duncan et al., 2007). Less well understood is *how* social behavior affects students' learning. This study was designed to examine evidence for different explanations for the association, including the role that children's relationships with their teachers plays in mediating the effects of social behavior on students' academic engagement and achievement.

We focused on aggressive behavior, a form of externalizing against peers. Recent studies on children's aggression have distinguished between overt physical aggression, found more commonly among boys than girls, and "relational aggression" (social or indirect aggression, such as excluding a child from play), found more commonly among girls (e.g., Crick, Grotpeter, & Bigbee, 2002; see Crick et al., 1999, for a review). The current study focuses on what is usually referred to as physical aggression. Because we relied on teacher ratings, we did not differentiate aggression based on different reasons—instrumental versus reactive—as a few researchers have done in past studies (e.g., Little, Brauner, Jones, Nock, & Hawley, 2003).

In a review focusing on externalizing behavior, Hinshaw (1992) summarizes evidence on four possible explanations for associations with achievement: (a) achievement affects externalizing behavior, (b) externalizing behavior affects achievement, (c) there is a reciprocal relationship between externalizing behavior and achievement, and (d) some third variable affects both externalizing behavior and achievement similarly. Analyses for the current study are based on this framework, extended to assess mediators of the association between aggression and achievement.

Evidence

Looking across extant studies, there is evidence for all of Hinshaw's (1992) explanations. First, results of some studies suggest that achievement affects students' social behavior. Miles and Stipek (2006), for example, found that poor literacy achievement in first and third grades predicted relatively high aggressive behavior in third and fifth grades, respectively. In a study on Australian children, Jorm, Share, Matthews, and Maclean (1986) found no differences in children's antisocial behavior in kindergarten as a function of reading skills, but the children who had reading difficulties were significantly more antisocial than the normal readers by the end of first and second grades. Williams and McGee (1994) similarly found that boys with reading disabilities at age 9 were more likely to develop a conduct disorder at age 15.

The data came from the school transition study, which followed approximately 400 low-income children and families from kindergarten or the first grade through the fifth grade. Principal investigators include Deborah Stipek, Penny Hauser-Cram, Walter Secada, Heather Weiss, and Jennifer Greene. Funding for the study was received from the MacArthur Foundation, the Department of Education, and the Foundation for Child Development. The authors are grateful to Tricia Valeski for her contributions to the conceptualization of this study.

Finally, McGee, Williams, Share, Anderson, and Silva (1986) reported that children who were having considerable difficulty learning to read at the beginning of school already showed behavior problems. Behavior problems also increased from ages 5 to 9 at a much faster pace for children who had serious reading difficulties than for other children.

The present study investigates further evidence related to possible effects of achievement on aggression, employing growth curve analysis to assess the degree to which change in achievement from kindergarten or first grade to fifth grade on an experimenter-implemented test predicted change in the amount of aggression rated by teachers over those grades.

There is also evidence for Hinshaw's (1992) second explanation that conduct problems affect academic achievement. Aggression and other externalizing behaviors may directly affect engagement and learning. For example, children who are aggressive may spend relatively more time misbehaving or being disciplined, reducing the amount of time they have to spend engaged in academic work. Consistent with this proposal, Coie and Dodge (1988) found that first- and third-grade students who were aggressive were more likely to be reprimanded by the teacher and spent less time "on task" than other children. Arnold (1997) similarly observed that misbehavior (aggression, hostility, and noncompliance) predicted low on-task behavior in their study of 4- to 6-year-old boys. The misbehavior prompted teachers to remove boys from the activity, and presumably as a consequence, they spent less time learning the material presented during that lesson. Accordingly, the present study assessed the degree to which changes in aggression predicted changes in achievement.

Aggressive behavior may also undermine engagement and learning indirectly. In this study, we test the hypothesis that the effect of aggression on students' engagement and learning is mediated by the relationships students develop with their teachers. Specifically, we propose that aggressive children form conflictual relationships with teachers, which presumably diminish their desire to engage in the work the teacher gives them and thus undermines their academic engagement and achievement. Our hypothesis is based on a set of empirical findings, summarized in the following, which support each of the links in the model we propose. Taken together, the evidence suggests the model, but it has not been previously tested directly.

Our prediction that children who are relatively more aggressive would develop more negative relationships with their teachers is consistent with previous research showing that teachers claim to have more conflictual relationships with children who exhibit antisocial behaviors (e.g., Birch & Ladd, 1998; Hamre & Pianta, 2001; Howes, Phillipson, & Peisner-Feinberg, 2000; Ladd, Birch, & Buhs, 1999; Ladd & Burgess, 2001; Pianta & Steinberg, 1992; Silver, Measelle, Armstrong, & Essex, 2005), and one study in which low-income kindergarten children's own ratings of the amount of conflict they had with their teachers were associated with teachers' ratings of their conduct problems (Mantzicopoulos, 2005).

The causal relationship between children's social behavior and their relationships with teachers is most likely reciprocal. For example, Hamre and Pianta (2001) found that among children who were identified as having behavior problems in kindergarten, those who developed relationships with teachers characterized by low levels of conflict and dependency had fewer discipline problems and more positive motivation than their counterparts through eighth grade. Silver et al. (2005) reported that conflict in the teacher–child relationship in kindergarten predicted faster rates of increase in aggressive behavior from kindergarten through third grade. To examine the possibility of a reciprocal relationship, we assess how well changes in teacher–child conflict predicted changes in aggressive behavior, as well as how well changes in aggressive behavior predicted teacher–child conflict.

Several studies have demonstrated associations between teacher–child relationships and academic performance for elementary-aged children (Birch & Ladd, 1997; Furrer & Skinner, 2003; Ladd & Burgess, 2001; Mantzicopoulos, 2005; Pianta & Stuhlman, 2004) and adolescents (e.g., Crosnoe, Johnson, & Elder, 2004; Gregory & Weinstein, 2004). Connell and his colleagues (Connell, 1990; Connell & Wellborn, 1991; Skinner & Belmont, 1993; see also Ryan & Deci, 2000) developed a self-system model to explain the effect of teacher–child relationships on children's learning behavior and achievement. According to Connell, children's motivation to engage in particular activities is determined in part by whether these activities take place in a context that satisfies their need for belonging or being socially connected. Children who feel a sense of belonging and social support adopt or internalize the goals and values of their teachers, such as active engagement and participation in school work (Deci & Ryan, 1985; Wentzel, 1997; see also National Research Council Committee on Increasing High School Students' Engagement and Motivation to Learn, 2004). In contrast, children who have conflict with their teachers are likely to feel alienated and consequently disengage from sanctioned classroom behavior (Connell, 1990; Lynch & Cicchetti, 1997).

There is some empirical evidence to support the proposed effects of negative relationships with teachers on adaptive participation (e.g., Birch & Ladd, 1998; Ladd et al., 1999). For example, in a study following children from kindergarten through eighth grade, Hamre and Pianta (2001) found a negative association between teacher – child conflict in kindergarten and children's positive work habits in first through fourth grades and with disciplinary problems in fifth and sixth grades. Ladd and Burgess (2001) found that children who had "chronic" levels of teacher – child conflict in kindergarten and first grade demonstrated relatively less cooperative participation (accepted the teacher's authority, complied with classroom rules). Children with whom teachers claimed to have relatively more conflictual relationships were thus at greater risk for poor academic achievement.

We did not expect teacher – child relationships to account for the entire association between aggression and achievement, given substantial evidence supporting Hinshaw's (1992) "third-variable" explanation. Many studies have shown that aggression and conduct disorders are strongly associated with hyperactivity and attention/distractibility problems (Connor et al., 2003; Fergusson & Horwood, 1995; Frick et al., 1991; Johnson, McGue, & Iacono, 2005; Spira & Fischel, 2005), which are also associated with poor academic achievement or underachievement (Frick et al., 1991; Hinshaw, 1992; Horn & Packard, 1985; Rabiner, Coie, & the Conduct Problems Prevention Research Group, 2000; Spira & Fischel, 2005; Velting & Whitehurst, 1997). Attention problems are not viewed as a mediator of the effects of aggressive behavior on achievement, but researchers who have attempted to separate their effects conclude that what appears to be an effect of conduct behaviors on achievement in elementary school can be explained substantially by the comorbidity of conduct disorders and hyperactivity/attention/distraction problems (Fergusson & Horwood, 1995; Frick et al., 1991; Hinshaw, 1992; Johnson et al., 2005). The independent effect of conduct on achievement appears to increase, however, in adolescence (Hinshaw, 1992). Most of these studies are based on clinical populations—children who have been diagnosed with attention-deficit hyperactive disorder, conduct disorders, and underachievement (a significant difference between actual achievement and achievement that would be predicted by IQ)—in contrast to the current study, which included mostly children who had no such diagnosis. This body of evidence is mentioned, however, because it reminds us that there are most likely a variety of valid explanations for associations between conduct and achievement and evidence for one explanation does not preclude the validity of another.

Children in this study were followed from kindergarten or first through fifth grades. Although we expected conflictual student – teacher relationships to mediate the effects of aggression on engagement and academic achievement for all these elementary grades, we took advantage of the longitudinal data to assess possible changes in the nature of the relationships over time. We also assessed gender differences, to determine whether boys were more prone to developing negative relationships that could undermine their engagement and learning, as is suggested by some previous studies discussed in the following, and to assess possible differences between boys and girls in the pattern of associations over time among the variables studied.

Gender Differences

Many previous studies have found girls to exhibit more prosocial and less antisocial behavior, and to have closer and less conflictual relationships with their teachers (e.g., Birch & Ladd, 1997; Bracken & Crain, 1994; Furrer & Skinner, 2003; Hamre & Pianta, 2001; Howes et al., 2000; Hughes, Cavell, & Willson, 2001; Kesner, 2000; Ryan, Stiller, & Lynch, 1994; Saft & Pianta, 2001; Silver et al., 2005). As noted by Hamre and Pianta (2005), because of the high percentage of female teachers, it is difficult to determine whether girls' advantage is related to the greater likelihood that their teacher is the same gender. The present study, like most, included too few male teachers to assess the effects of the teacher gender, but the design did allow us to assess gender differences in children from kindergarten or first grade through the fifth grade on these dimensions. Moderator effects of gender were also assessed in the longitudinal analyses, although we had no basis for making specific hypotheses.

The children in the study were ethnically diverse and came from very low-income families. This population was studied because although low-income children and children of color have, on average, the poorest achievement outcomes, most of the research on social skills and relationships in school involve middle-class samples. An understanding of the way social variables affect achievement in the children who are most at risk of school failure could help guide interventions designed to close the achievement gap. Previous studies have not focused on low-income children who are most at risk of poor performance, few have followed children for as long as 6 years through elementary school, and none have examined simultaneously direct effects of children's aggression on academic engagement and the effects of aggression on achievement mediated by relationships with teachers.

Method

Participants

Children. Participants of the original sample included 403 children (51.7% girls) who were participating in a longitudinal study on transition to school, although for most analyses, given missing data and attrition, there were approximately 300 children. Children were followed from kindergarten ($N = 283$) or first grade ($N = 120$) through the fifth grade. Some of the children had already completed kindergarten when the study began and thus could not begin their participation until the first grade. Kindergarteners and first graders were combined for analyses. The children who entered the study at either kindergarten or first grade were reassessed in second, third, and fifth grades. Analyses at each grade level included all the children in the longitudinal sample for whom relevant data were available at that grade level.

The families of all participating children had incomes below the federal poverty guidelines when they entered the study. At the start of the present study, most (76%) household incomes were below $15,000, 21% were below $6,000, most (62%) mothers were not married, and 49% were not working. With regard to education, 13% of the primary caretakers interviewed had less than the equivalent of a ninth-grade education and 28% went past the ninth grade but did not complete high school.

Of the participating children, 35% are African American, 34% are White, 28% are Latino, 2% are Asian, and 1% is Native American. Approximately 38% of the Latino children were not proficient in English at the beginning of the study. Children lived in three geographical areas of the United States: a rural and an urban area in the Northeast and a West Coast urban area.

Overall, attrition in the study was modest (less than 19% over a period of 6 years). Analyses comparing children who were lost to those who were still in the sample at fifth grade revealed no significant differences in family income, gender, or cognitive skills (measured at 60 months, before the present study began). A chi-square analysis of ethnic differences in attrition rates was, however, significant, $\chi^2(4) = 18.62$, $p \leq .001$. A higher proportion of Latino children were lost than either African American or Caucasian children.

Teachers. All teachers who had a study child enrolled in their classroom were invited to participate in the study. By the fifth grade, children were enrolled in 233 classrooms in 138 schools. The modal number of study children per classroom was 1. Teacher experience varied from 1 to 38 years of teaching, with a mean of 16 years. Almost all teachers (99%) had at least a bachelor's degree; 45% had a master's degree.

Procedures and Measures

Teacher questionnaires. In the spring of each year, questionnaires were mailed or delivered to teachers of participating children. Teachers responded to questions regarding an individual child's aggressive behavior, academic engagement, and teacher–child conflict. The average return rate for questionnaires was 75%.

Aggressive behavior. Teachers rated children's aggression using a subscale of the Child Behavior Scale, developed by Ladd and Profilet (1996). Four items (e.g., "fights with other children," "aggressive child," "taunts/teases other children," "bullies other children") were used, with a 3-point response format (*does not apply, applies sometimes, certainly applies*). Alpha coefficients were .91, .92, and .91 for kindergarten/first, third, and fifth, grades, respectively.

Teacher–child conflict. Teachers rated the degree to which they had a relationship that involved conflict for the individual child at each grade level using items from the conflict subscale of Pianta's Student–Teacher Relationship Scale (Pianta, 1994; Pianta & Steinberg, 1992; Pianta, Steinberg, & Rollins, 1995). Each item has a 5-point response scale (*definitely does not apply, not really, neutral/not sure, applies somewhat, definitely applies*). In consultation with the scale's author, 5 of the original 12 items from the conflict subscale were selected to diminish the burden on teachers (e.g., "this child and I always seem to be struggling with each other," "this child easily becomes angry with me"). The alphas for this scale were .89, .89, .92, and .88 for kindergarten/first, second, third, and fifth, grades, respectively.

Academic engagement. Teachers rated children's academic engagement—the degree to which an individual student is responsibly engaged with academic work—using items from the Teacher Rating Scale of School Adjustment (TRSSA) developed by Birch and Ladd (1997). Three of the items were taken from the self-directedness subscale of the TRSSA (e.g., "seeks challenges," "works independently"), and one of the items was from the cooperative participation subscale ("accepts responsibility for a given task") of the TRSSA. The items all have a 3-point response format (*does not apply, applies sometimes, and certainly applies*). Reliabilities for these four items were acceptable for each grade level (alphas = .87, .84, .83, and .85 for kindergarten/first, second, third, and fifth, grades, respectively).

Academic achievement. Children's math and literacy skills were assessed individually in the spring of kindergarten or first grade, and again in third and fifth grades, by a trained experimenter. The literacy and most of the math assessments were available in Spanish. The sections of the math assessment that were not available in Spanish were translated. Children who preferred the Spanish version were assessed by a native Spanish speaker. The number of children who were assessed in Spanish ranged from 38 (kindergarten/first) to 0 (fifth grade).

To ensure a range of scores and a broad array of math skills, kindergarteners and first graders were given a math test that included items from the Woodcock–Johnson Psychoeducational Battery–Revised (WJ–R) calculations subtest (Woodcock & Johnson, 1989), identification of written numbers and shapes from the Peabody Individual Achievement Test–Revised (Dunn & Dunn, 1981), word problems involving addition and subtraction developed by cognitively guided instruction (CGI) researchers (Carpenter, Ansell, Franke, & Fennema, 1993; Carpenter, Fennema, & Franke, 1996), questions about relative size (e.g., "which is more, 5 or 6?") from the Test of Early Mathematics Ability (Ginsburg & Baroody, 1990), and set of counting items (e.g., counting 50 blocks, counting from 90 to 120, and counting up or down from a specified number; Secada, 1991). Scores for each of these sets of items reflected the proportion of items answered correctly. The third- and fifth-grade math assessments included two subtests from the WJ–R: calculation and applied problem solving. Scores were calculated according to the manual instructions—the item number of the most difficult item answered correctly before missing five problems in a row minus the number of items missed since the basal item (based on the lowest of five items the student answered correctly). In addition to these two WJ–R subtests, children were given additional word problems taken from CGI research projects (Carpenter et al., 1993; Carpenter et al., 1996). Third graders received one additional set of CGI problems that involved counting using individual and sticks of 10 unifix cubes. The total math achievement score was calculated by standardizing the score for each subtest within grade and averaging them. Alpha reliability coefficients ranged from .55 (third grade) to .80, with an average of .71. We suspect that the relatively low alpha in math for third graders is a consequence of items (e.g., using unifix cubes) that were unfamiliar to some children.

For literacy achievement, two subtests of the WJ–R were used for the third and fifth graders: the letter–word reading and the passage comprehension. The first test asks children to decode single words. In the second, children read a passage and fill in a missing word. The WJ–R letter–word identification subscale was adapted for the kindergarten and first graders to ensure enough items at their level to show some variability in scores. (Pilot testing revealed a floor effect.) Thus, instead of asking children to identify only the 9 letters in the WJ–R, they were shown all 26 letters of the alphabet. Kindergarten and first-grade children were also given a larger number of simple (2 to 4 letters) words to identify than are provided in the WJ–R. The WJ–R was supplemented at all grades with the Saunders (1999) performance-based test, which assesses writing, comprehension, and reading and verbal fluency. Children were dictated letters (kindergarten only), words, and sentences to write. Scores reflected the proportion of letters or words written correctly. Comprehension was assessed by reading a passage to the child (kindergarten) or having a child read a passage (first, third, and fifth grades), and asking a series of questions about the story. Answers were rated on a 1–3 scale for their correctness, and these scores were averaged to create a comprehension score. Overall verbal fluency was rated on a 0 (practically nonverbal) to 2 (verbal, fluent, talkative; gave detailed answers) scale. Reading fluency was assessed on a 0 (nonreader) to 6 (reads words fluently) scale. All subscale scores were converted to standardized scores and then combined within each grade to create an overall mean literacy achievement score. Alphas for the literacy scores at each grade ranged from .74 to .82, with an average of .79.

Assessments of children's math and literacy skills were highly correlated at every grade (.58, .55, and .55 for kindergarten/first, third, and fifth grades, respectively, all $ps \leq .001$). Because we had no reason to expect aggression to affect or be affected differently by math and literacy skills, standardized scores for the two subject areas were combined to form one measure of academic achievement. The alphas for this combined achievement measure were .73, .72, and .71 for kindergarten/first, third, and fifth grades, respectively.

Results

The percentage of children missing data on the variables included in this study ranged from 8% to

24% of the sample. Children with missing data did not differ significantly from children without missing data on ethnicity or gender, with one exception. Latino children were more likely to have missing teacher-reported data in Grades 1, 3, and 5 than White and African American children. Because hierarchical linear modeling (HLM) allows for ignorably missing data through its use of weighting and smoothing techniques, no imputations were made and all data were used in the growth curve analysis. For the path analysis, only the participants who had complete data at each grade level were included.

Table 1 presents the means and standard deviations, by gender, for all variables used in analyses. The distributions for aggression were positively skewed, with Pearson skewness coefficients ranging from 1.17 to 1.34. The distribution of teacher – child conflict ratings were also positively skewed, with Pearson skewness coefficients ranging from .98 to 1.41. Log transformation of these variables did not affect the findings.

Interconstruct and Intragrade Correlations

As a first step in testing the hypotheses, correlations among all the variables of interest were computed (see Table 2). As expected, and consistent with previous research (e.g., Birch & Ladd, 1998), children's aggression ratings were generally positively associated with teacher – child conflict and negatively associated with academic engagement and achievement. Teacher – child conflict, in turn, was generally negatively associated with academic engagement and achievement, and academic engagement was significantly correlated with academic achievement. The one notable anomaly was that academic achievement was not associated with either aggression or teacher – child conflict at third grade. Intergrade correlations shown in Table 3 indicate a fair amount of stability in all the variables studied.

Explanations for Associations Between Aggression and Achievement

Growth curve analyses. Growth curve analysis using HLM 6.21 (Raudenbush & Bryk, 2002) was used to test three sets of hypotheses bearing on different explanations for the association between aggression and achievement: (a) that changes in achievement predict changes in aggression, (b) that changes in aggression predict changes in achievement, and (c) that the effect of aggression on achievement is mediated by teacher – student relationships. To assess the mediation hypothesis we first tested each of the proposed links in the model: (a) changes in aggression predict changes in teacher – child conflict, (b) changes in teacher – child conflict predict changes in engagement, which (c) in turn predict changes in academic achievement. We then tested the mediation hypothesis more directly by assessing the hypothesis that (d) increases in aggression no longer predict changes in achievement with mean teacher – child conflict (and in a subsequent analysis, mean engagement) held constant.

HLM was used because it estimates individual and group growth curves simultaneously to describe patterns of change over time. The individual growth curves can be predicted from time-varying variables as well as testing mediation and moderation effects of between-subjects and time-invariant factors, such as gender and mean teacher – child conflict, and HLM can accommodate missing values.

Table 1
Means and Standard Deviations for Aggression, Teacher – Child Conflict, Engagement, and Achievement, by Gender

	Aggression	Conflict	Engagement	Achievement
Kindergarten/first grade				
Boys (n = 151)	1.55 (.55)	1.89 (0.98)	2.28 (.51)	−0.02 (0.66)
Girls (n = 150)	1.37 (.42)	1.70 (0.91)	2.40 (.56)	0.03 (0.73)
Second grade				
Boys (n = 162)	1.57 (.64)	2.04 (1.00)	2.07 (.53)	—
Girls (n = 168)	1.36 (.42)	1.74 (0.78)	2.26 (.40)	—
Third grade				
Boys (n = 162)	1.54 (.53)	2.00 (1.00)	2.11 (.46)	−0.03 (0.65)
Girls (n = 166)	1.39 (.49)	1.71 (0.91)	2.20 (.52)	0.01 (0.60)
Fifth grade				
Boys (n = 137)	1.58 (.60)	2.16 (0.96)	2.04 (.51)	−0.09 (1.34)
Girls (n = 143)	1.27 (.47)	1.67 (0.89)	2.24 (.52)	0.14 (1.29)

Table 2
Correlations Among Constructs, Within Grades

	Conflict	Engagement	Achievement
Kindergarten/first grade			
Aggression	.48***	−.29**	−.14**
Teacher–child conflict		−.52***	−.18**
Engagement			.44***
Second grade			
Aggression	.70***	−.35***	—
Teacher–child conflict		−.46***	—
Engagement			—
Third grade			
Aggression	.65***	−.26***	−.07
Teacher–child conflict		−.40***	−.02
Engagement			.30***
Fifth grade			
Aggression	.20**	−.29**	−.24**
Teacher–child conflict		−.45***	−.20**
Engagement			.30***

Note. The sample sizes were 301 for kindergarten/first grade, 330 for second grade, 228 for third grade, 280 for fifth grade; no achievement test was given in second grade.
$^{**}p \leq .01$. $^{***}p \leq .001$.

For each model tested, the Level 1 model looked as such,

$$y_{it} = \pi_{0i} + \pi_{1i} \times (\text{Grade}_{it}) + \pi_{2i} \times (\text{Grade} \times \text{Predictor}_{it}) + e_{it}.$$

The term y_{it} is the outcome variable for child i at time t and is a linear function of the child's grade in school on that occasion plus random error (e_{it}). The equation stipulates that the trajectory is linear across time and has the growth parameters: π_{0i}, π_{1i}, and π_{2i}. A linear model was used because we had just three time points.

The intercept π_{0i} should be interpreted as each child's mean score of the outcome variable at the initial time, which is in either kindergarten or first grade. The second parameter, π_{1i}, represents the slope of the outcome variable or the rate the individual child changes across the grades (coded as *kindergarten or first grade* = 1, *third grade* = 3, and *fifth grade* = 5). Second grade was not included in this analysis because an independent achievement assessment was not given in second grade. The third parameter, π_{2i}, represents the rate of change on the outcome variable over time, taking into account change in the predictor. This parameter tests whether changes in the predictor across grades is associated with changes in the outcome variable. The random error for child i at time t is represented in the equation as e_{it}. This may be interpreted as the measurement errors associated with the differences between the true and observed growth trajectories.

The first model (Model 1) tested whether changes in achievement predicted changes in aggression. As seen in Table 4, the estimation of fixed effects indicates that change over time in children's achievement was a marginally significant predictor of change over time in children's aggression ($\beta = -.01$, $p \leq .10$); on average, an increase in achievement was associated with a decrease in aggression.

The second model (Model 2) tested whether changes in aggression across the grades predicted changes in achievement. The results (Table 4) indicate that on average an increase in aggression was significantly associated with a decrease in achievement ($\beta = -.09$, $p \leq .05$).

The third set of models (Models 3a, 3b, 3c) tested whether (a) changes in aggression predicted changes in teacher–child conflict, (b) changes in teacher–child conflict predicted changes in engagement, and (c) changes in engagement predicted changes in children's achievement (see Table 4). The results indicate that changes in aggression significantly predicted changes in teacher–child conflict; an increase in aggression was associated with an increase in conflict ($\beta = .31$, $p \leq .001$). In addition, an increase in conflict significantly predicted a decrease in engagement ($\beta = -.07$, $p \leq .001$). Last, an increase in engagement was significantly associated with an increase in achievement ($\beta = .19$ $p \leq .001$).

Table 3

Intergrade Correlations

	Second grade	Third grade	Fifth grade
Aggression			
Kindergarten/first grade	.54***	.32**	.48***
Second grade		.27***	.56***
Third grade			.35***
Teacher–child conflict			
Kindergarten/first grade	.47***	.39***	.28***
Second grade		.43***	.33***
Third grade			.37***
Engagement			
Kindergarten/first grade	.33***	.29***	.35***
Second grade		.45***	.16*
Third grade			.32***
Achievement			
Kindergarten/first grade	—	.65***	.58***
Third grade			.71***

Note. The sample sizes are 301 for kindergarten/first grade, 330 for second grade, 228 for third grade, 280 for fifth grade; no achievement test was given in second grade.
$^*p \leq .05$. $^{**}p \leq .01$. $^{***}p \leq .001$.

To assess the goodness of fit of the models tested, a comparison of the deviance and the chi-square statistics among models was conducted. The deviance statistic of a full maximum likelihood model reflects the fit of the entire model and signifies how much worse the current model is when compared to the best possible model. Thus, the smaller the absolute value is, the closer the fit to the best possible model (Singer & Willett, 2003). For Models 1–3, the deviance statistics were as follows: Model 1 = 2,502.23, Model 2 = 1,577.92, Model 3a = 2,683.24, Model 3b = 1,822.39, and Model 3c = 4,171.74. The chi-square statistics also indicate the relative fit of a model to the data. In the present study, none of the models' chi-square statistics were significant (all $ps \leq .50$). Thus, we are able to reject the null hypotheses for all models, which is desired when testing the fit of a model.

Gender differences. To assess the role of gender (coded as 1 = boys, 0 = girls) in the growth curve analyses, gender was included in the earlier models at the second level, such that:

$$\pi_{0i} = \beta_{00} + \beta_{01} \times (\text{gender}) + r_0$$

$$\pi_{1i} = \beta_{10} + \beta_{11} \times (\text{gender})$$

$$\pi_{2i} = \beta_{20} + \beta_{21} \times (\text{gender})$$

Results (see Table 4) indicate that gender significantly predicted initial differences in aggression, teacher–child conflict, and student engagement; on average, boys had significantly higher ratings of aggression ($\beta = .13, p \leq .05$) and teacher–child conflict ($\beta = .22, p \leq .05$), and, initially, girls had significantly higher engagement ($\beta = -.16, p \leq .01$). The test of gender differences in initial achievement was not significant. Gender did not show any significant effects on changes in these four variables across grades and gender did not moderate the effect of the predictor on the outcome in any analysis (see Table 4).

Mediational models. Finally, we tested directly whether mean teacher–child conflict or student engagement mediated the relationship between aggression and achievement. Mean teacher–child conflict and student engagement were added into the Level 2 model separately such that:

$$\begin{aligned}\pi_{0i} = {} & \beta_{00} + \beta_{01} \\ & \times (\text{mean teacher–child conflict or engagement}) \\ & + r_0 \\ \pi_{1i} = {} & \beta_{10} + \beta_{11} \\ & \times (\text{mean teacher–child conflict or engagement}) \\ \pi_{2i} = {} & \beta_{20} + \beta_{21} \\ & \times (\text{mean teacher–child conflict or engagement})\end{aligned}$$

As shown in Table 5, the results indicate that neither mean teacher–child conflict ($\beta = .05, p = .31$) nor mean student engagement ($\beta = .04, p = .50$) significantly mediated the effect of changes in aggression on changes in achievement.

Within-grade path analyses. The growth curve analyses have several limitations. They do not allow a test of the full hypothesized causal model (aggression → teacher–child conflict → low engagement → low achievement). Second, because there are only three time points, it cannot be determined whether the significant effect is primarily based on predictions from kindergarten/first to third grade or third grade to fifth grade. A related limitation is that they take good advantage of the longitudinal data, but they do not tell us whether the hypothesis is supported within each grade.

Path analyses were therefore conducted to test the mediation hypothesis at individual grade levels. In the model was a path that included the mediators (teacher–child conflict and engagement) as well as a direct path from aggression to academic achievement. To assess the overall fit of each model at

Table 5

each grade level, LISREL 8 (Jöreskog & Sörbom, 1993) was used. In addition, all path coefficients in Figures 1a – 1c are standardized beta coefficients.

Figure 1a shows the results of the path analysis for kindergarten/first grade. The results from the various tests of model fit allow us to conclude that the specified kindergarten/first-grade model fit the data well. The chi-square test ($\chi^2 = 2.68$, $p = 0.26$) was not statistically significant; that is, we failed to reject the null hypothesis, which is desired in testing a model. The root mean square error of approximation (RMSEA) was 0.03. Byren (1998) notes that a model with RMSEA values less than 0.05 indicates a good fit, whereas values ranging from 0.08 to 0.10 indicate a mediocre fit. The goodness of fit index (GFI), in which 0.9 indicates a relatively good fit, was 0.98. The results from the individual paths show that the paths from aggression to teacher – child conflict, conflict to engagement, and engagement to achievement are significant but the direct path from aggression to achievement is not significant.

Figure 1b shows the results of the path analysis for third grade. The results from the various tests of model fit allow us to conclude that the specified third-grade model fit the data well. The chi-square test ($\chi^2 = 3.54$, $p = 0.17$) was not statistically significant and the RMSEA was 0.05. The GFI was 0.97. Similar to the results in kindergarten/first grade, the paths from aggression to conflict, conflict to engagement, and engagement to achievement were significant, whereas the direct path from aggression to achievement was not.

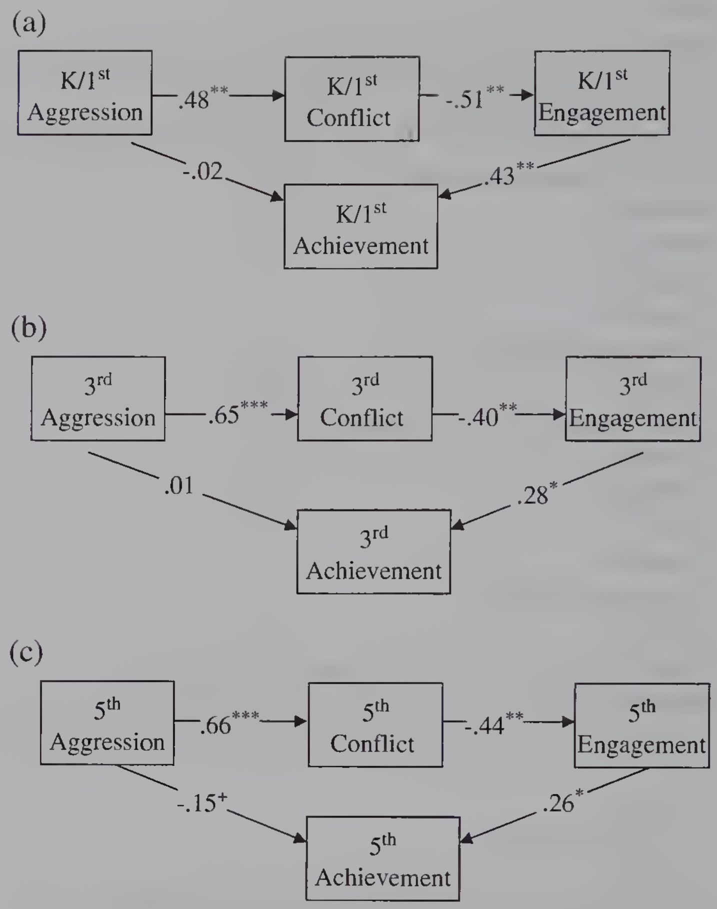

Figure 1. Path analysis results, predicting achievement within grade: (a) kindergarten/first grade, (b) third grade, and (c) fifth grade. $^{*}p \leq .05$. $^{**}p \leq .01$. $^{***}p \leq .001$.

Figure 1c shows the results of the path analysis for fifth grade. The results from the various tests of model fit allow us to conclude that the specified fifth-grade model fit the data fairly well. The chi-square test ($\chi^2 = 1.41$, $p = 0.52$) was not statistically significant. The RMSEA of 0.09 indicated a mediocre fit and the GFI was .95. All the paths representing the mediation hypothesis had significant standardized beta coefficients. Unlike the findings for the younger grades, in which the direct path from aggression to achievement was not significant, for fifth grade it was marginally significant.

In summary, the path analyses are consistent with the hypothesis that the effect of aggression on academic achievement is at least partially mediated by its effects on conflict with teachers and the resultant lowered engagement in academic work. The direct path between aggression and achievement was not significant, although by fifth grade, it was almost significant.

Predicting Aggression From Teacher – Child Conflict

As discussed earlier, there is evidence suggesting that teacher – child relationships are both affected by and affect children's social behavior. In the aforementioned analyses, teacher – child conflict was predicted by children's aggression. In the next analysis we assess evidence for a relationship in the opposite direction. Results of a growth curve analysis (see Table 4, Model 4) indicate that changes in teacher – child conflict significantly predicted changes in aggression; an increase in conflict across the grades was associated with an increase in aggression (β = .08, $p \leq .001$). The deviance statistic to test the goodness of fit for Model 4 was 1,250.31 and the chi-square statistic measuring the homogeneity of the Level 1 variance was nonsignificant, suggesting a good fit.

To assess whether the effect of teacher–child conflict on the change in aggression was different for boys than girls, gender (coded as 1 = *boys*, 0 = *girls*) was included in Model 4 at the second level. The results (see Model 4, Table 4) of the main effect of gender on the change in aggression indicate that gender significantly predicted initial differences in aggression, with boys, on average, having significantly higher ratings in aggression (β = .17, $p \leq .01$). However, the test of gender differences in change in aggression was not significant (β = −.04, $p = .12$).

Discussion

This study examined several alternative, although not mutually exclusive, explanations for the association often found between aggression and achievement (see Duncan et al., 2007, for an exception in that it found few significant associations between social behavior and school performance). The study also assessed gender differences on these dimensions and in the pattern of relationships among them. These topics are discussed in the following.

Explanation of Aggression–Achievement Association

The significant cross-grade correlations are consistent with previous studies suggesting that children's social behavior remains relatively stable over the first few grades of school (e.g., Birch & Ladd, 1998; Ladd & Burgess, 2001; Ladd & Profilet, 1996; Silver et al., 2005). Nevertheless, changes that were seen in children's aggression predicted changes in achievement, suggesting that aggression may undermine achievement. There was also some, albeit weaker, evidence for the view that poor academic achievement promotes aggression.

Why might academic skills affect children's behavior? We have previously proposed that children who find schoolwork difficult may become frustrated or unhappy in school and express their frustration and unhappiness by acting aggressively (Miles & Stipek, 2006). Our proposal is based on an early theory that frustration (defined as the state that emerges when circumstances interfere with a goal response) leads to aggression (Dollard, Doob, Miller, Mowrer, & Sears, 1939). Berkowitz (1968) suggested that any unpleasant emotion and feeling, such as anxiety, anger, and annoyance, can trigger either "fight or flight." There is some empirical evidence for the theory (see Berkowitz, 1978; Buss, 1963). Rutter and Guller (1983) proposed a somewhat different but related explanation for the effect of poor achievement on aggression. They suggested that academic failure leads to low self-esteem and general antagonism toward school, which in turn prompts negative behaviors.

By fifth grade, there was some weak evidence for a direct effect of aggression on achievement. But most of the findings were consistent with our hypothesis that the effect of aggression on achievement is partially mediated by its effects on teacher–child relationships. The growth curve analyses supported each link in the model, showing that changes in aggression significantly predicted changes in the amount of teacher–child conflict, which in turn predicted changes in students' engagement, which predicted changes in students' achievement. Although gender was associated with mean initial scores on all but the achievement measure, gender did not moderate the associations found among the variables. The mediation hypothesis was also supported by path analyses within each grade evaluating the entire model, although not in the growth curve analysis. The failure of the test of the mediators in the growth curve analyses may have occurred because only the average of the mediator over the three grades could be tested, not change over time in the mediators, and teacher–child conflict and engagement had to be tested in separate analyses. Although the growth curve analysis took advantage of the longitudinal data, it was not the most effective way to assess the full mediation model.

There are many reasons why developing a conflictual relationship with the teacher might undermine academic engagement and learning. For example, children who have relatively high amounts of conflict with the teacher may develop generally negative feelings about the teacher and school, and as a result lack motivation to engage in the academic work the teacher assigns. Teachers may also report a conflictual relationship with the children they discipline relatively often; the frequent experience of being disciplined may contribute to the children's negative feelings as well as take time away from academic work.

The results of this study highlight the importance of helping children develop self-regulation, anger management, and social problem-solving skills. Even if academic performance is the primary concern, there may be value in investing time and effort in children's social experiences and skills. Positive social skills and relationships might serve as important protective mechanisms against academic failure, which might be particularly important for low-income children, who are often found to be at risk for poor academic performance.

Relationships with teachers and engagement, as measured in this study, did not completely explain the effects of aggression on achievement. In the longitudinal analyses changes in aggression continued to predict changes in achievement, with mean teacher–child conflict and with mean engagement held constant. And for fifth graders, the direct path from aggression to achievement was marginally significant. Also, despite the consistently strong associations found between aggression and achievement, the results of this study do not rule out the possibility that aggression is not really the culprit but rather other problems that co-occur with aggression undermine academic achievement. Previous research, mentioned earlier, suggests that hyperactivity and accompanying attention problems are really at fault, not aggression. Most previous studies on hyperactivity and attention problems included children who were diagnosed with significant problems on these dimensions. It would be useful in future studies to assess the independent effects of attention/hyperactivity and aggression on children's learning, both directly and indirectly, for children who cover a broader range on these dimensions.

Effect of Teacher–Child Conflict on Aggression

The study also examined whether teacher–child conflict predicted aggression, consistent with previous research, summarized earlier (e.g., Hamre & Pianta, 2001; Silver et al., 2005), suggesting that teacher–child relationships may promote or undermine positive behavior. As predicted, not only did changes in aggression predict changes in teacher–child conflict but the reverse was also true. Changes in teacher–child conflict also predicted changes in children's aggression. The findings are consistent, therefore, with a reciprocal relationship, with aggressive behavior generating conflict with teachers and conflict with teachers exacerbating children's aggressive behavior.

The findings that teacher–child conflict predicted both increased aggression and lower engagement suggest the importance of helping teachers avoid developing conflictual relationships with aggressive children. We recognize that this may be difficult, given that teacher behavior is in part a reaction to child behavior. But a preponderance of negative interactions with the teacher is not likely to support children's desire to engage in teacher-sanctioned activities. Efforts to ensure at least some positive interactions, for example, by engaging the more aggressive children in conversation about their interests, taking care to notice good behavior, and conveying high expectations, may compensate for the negative disciplinary interactions.

Gender Differences

As hypothesized, already by kindergarten or first grade, teachers rated boys as more aggressive and less engaged, and their relationships with girls as less conflictual. These findings are consistent with previous research (e.g., Birch & Ladd, 1997; Bracken & Crain, 1994; Furrer & Skinner, 2003; Hamre & Pianta, 2001; Howes et al., 2000; Hughes et al., 2001; Kesner, 2000; Ryan et al., 1994; Saft & Pianta, 2001; Silver et al., 2005) and have important practical implications. In light of evidence that social competence, teacher–child relationships, and academic engagement affect children's academic learning, the present study provides further evidence that boys are at greater risk of underachievement than girls. Given the possibility of a key role played by relationships with teachers in children's engagement and achievement, teachers might need to make extra efforts to develop positive relationships with boys, especially boys who are aggressive. Such efforts might serve as a protective factor and improve boys' academic success.

Limitations and Conclusions

This study relied substantially on teacher ratings. It would be useful in future studies to obtain independent assessments of children's aggression, relationships with teachers, and engagement in academic activities. Children's own perceptions related to all of these constructs would also be useful. Furthermore, data were gathered at one time point at each grade level. Future work could examine children's social competencies, relationships with teachers, and achievement at both the beginning and the end of each school year.

Despite some limitations, the study reminds us of the complexity of relationships among variables that affect student achievement. Many factors affect children's learning. This study, combined with previous research, suggests that even one factor, aggressive behavior, probably affects achievement in more than one way and that the relationship between aggression and achievement is very likely reciprocal. Developing analytic methods to assess these complex relationships is a challenge but an important goal of developmental research.

This investigation examined the associations between maltreatment and aggression using a gender-informed approach. Peer ratings, peer nominations, and counselor reports of aggression were collected on 211 maltreated and 199 nonmaltreated inner-city youth (*M* age = 9.9 years) during a summer day camp. Maltreatment was associated with aggressive conduct; however, these effects were qualified by gender, maltreatment subtype, and the form of aggression under investigation. Findings revealed that maltreatment was associated with physical aggression for boys and relational aggression for girls. Physical abuse was associated with physically aggressive behaviors, but sexual abuse predicted relational aggression for girls only. Findings suggest that investigating the interaction between familial risk and gender is important in understanding aggressive behaviors of boys and girls.

A robust finding in the maltreatment literature is the association between childhood abuse and externalizing difficulties, particularly children's aggression toward peers (Klimes-Dougan & Kistner, 1990; Salzinger, Feldman, Hammer, & Rosario, 1993; Shields & Cicchetti, 2001; Sternberg, Baradaran, Abbott, Lamb, & Guterman, 2006). Unfortunately, our understanding of these links for boys and girls is limited in several important ways. First, work is needed that extends definitions of aggression to forms that are salient to girls as well as boys (Crick, 1995). Second, few studies have examined the moderating effects of gender on the association between maltreatment and gender-salient forms of aggression. Finally, there is a paucity of research on the ways in which subtypes of maltreatment may interact with gender when predicting aggression among boys and girls. The present investigation represents an initial attempt to elucidate these processes by examining the patterns of associations between maltreatment and aggression using a gender-informed developmental approach.

Maltreatment and Aggression

The first goal of the present study was to gain a gender-balanced understanding of the association between maltreatment and aggressive conduct. A number of mechanisms have been posited to underlie the relation between maltreatment and aggression. Due to the inconsistent care and relational toxicity that exist in maltreating families, maltreatment may disrupt children's internal working models (i.e., the view of self as worthy and competent and of others as caring and responsive), which in turn place them at risk for heightened aggression (Cicchetti & Toth, 2005; Rogosch, Cicchetti, & Aber, 1995; Shields, Ryan, & Cicchetti, 2001). Consistent with this perspective, Shields et al. (2001) found that negative and constrictive representations of caregivers significantly increased the likelihood that maltreated children would exhibit aggression with peers. Children who carry these internal representations forward into their relationships with peers are likely to readily perceive threats from peers, misinterpret social cues from

others, and respond to peers with anger and aggression (e.g., Teisl & Cicchetti, 2008; Troy & Sroufe, 1987).

Findings from the maltreatment literature are also commensurate with a social-cognitive perspective of aggression (e.g., Bandura, 1986; Crick & Dodge, 1994). Physically abused children not only generate more aggressive solutions in the face of conflict but also view aggression as an effective way to meet their social and instrumental goals (Dodge, Bates, & Pettit, 1990; Herrenkohl, Egolf, & Herrenkohl, 1997; Shields & Cicchetti, 2001; Weiss, Dodge, Bates, & Pettit, 1992). In addition, children exposed to abuse and neglect encounter difficulties accurately interpreting social cues, with a greater tendency to perceive hostility and anger compared to children who have not been maltreated (e.g., Pine et al., 2005; Pollak, Cicchetti, Hornung, & Reed, 2000).

Maltreatment may also contribute to aggressive behavior by interfering with children's emotion regulation abilities. Children who experience maltreatment at the hands of significant others may internalize the experienced hostility, fear, and rejection in ways that lead to difficulties managing frustration and anger, competencies that are necessary for the successful resolution of peer conflicts (e.g., Shields & Cicchetti, 2001). In fact, maltreated children exhibit heightened arousal in response to other's distress or interpersonal conflict and display more anger than their nonmaltreated peers (Cummings, Hennessy, Rabideau, & Cicchetti, 1994; Klimes-Dougan & Kistner, 1990; Maughan & Cicchetti, 2002). Such difficulties have been found to mediate the relation between maltreatment and poor social competence with peers (Shields, Cicchetti, & Ryan, 1994).

A Gender-Informed Approach to the Study of Maltreatment and Aggression

Despite considerable theoretical and empirical work linking maltreatment and aggression, at present, we know very little about the ways in which gender may interact with maltreatment experiences in predicting aggression among boys and girls. We argue that a gender-informed approach capable of simultaneously modeling gender-balanced predictors and outcomes is needed. First, evidence suggests that boys and girls may differ in the ways they experience aggression (Archer & Coyne, 2005; Paquette & Underwood, 1999). Second, different etiologic risks may predict different aggression trajectories for boys and girls (e.g., Crick & Zahn-Waxler, 2003; Moffit & Caspi, 2001; Silverthorn & Frick, 1999). Based on this work, it would be important to examine how different forms of maltreatment, for example, physical and sexual abuse, interact with gender when predicting gender-relevant forms of aggression.

Relational aggression. A gender-informed approach should include relational as well as physical aggression for two reasons. First, although both boys and girls use physical and relational aggression, there are important differences. Boys tend to use physical force or make physical threats more than girls, and girls, when aggressive, are more likely to use relational, indirect, or social aggression over physical means (Archer & Coyne, 2005; Brendgen et al., 2005; Card, Stucky, Sawalani, & Little, 2008; Giles & Heyman, 2005; Ostrov & Keating, 2004). In this article, relational aggression will refer to overtly or covertly socially manipulating behaviors used to harm relationships between two or more individuals. These behaviors include withdrawing friendships, excluding others, or sabotaging someone's relationships with others by spreading vicious rumors (Crick, 1995; for discussion of indirect/social aggression, see Archer & Coyne, 2005; Björkqvist, Lagerspetz, & Kaukiainen, 1992; Galen & Underwood, 1997).

Second, mounting evidence suggests that girls are more attuned to and affected by relational conflicts than boys. Relative to boys, girls perceive relationally aggressive acts as mean and hurtful and experience heightened emotional and physiological distress in response to such behaviors (Coyne, Archer, & Elsea, 2006; Galen & Underwood, 1997; Giles & Heyman, 2005). Furthermore, whereas girls are more likely than boys to view relationally aggressive acts as wrong, boys are more likely than girls to view physically aggressive acts as wrong (Goldstein, Tisak, & Boxer, 2002; Murray-Close, Crick, & Galotti, 2006).

Relational aggression and maltreatment. Through many of the same mechanisms already discussed (e.g., biased social-cognitions, dysregulated affect), maltreated children may extend the relational hostility and confusion experienced within their family system into subsequent peer interactions by exhibiting relational aggression. For example, from a social information processing (SIP) perspective (Crick & Dodge, 1994), relationally aggressive children readily perceive threats in relational conflicts and use relationally aggressive behaviors to increase feelings of inclusion, control social connections, and reduce feelings of jealousy (Crick & Werner, 1998; Grotpeter & Crick, 1996). Maltreated children may learn through their interactions with caregivers that love and affection are given sporadically, can be withdrawn, and are used against others such that when confronted with relational threats in the peer context, they exclude or socially manipulate their peers. Likewise, because maltreatment and relational aggression are associated with heightened dysregulation in response to interpersonal conflicts (Coyne et al., 2006; Crick, Grotpeter, & Bigbee, 2002; Murray-Close & Crick, 2007; Shields et al., 1994), maltreated children may react to such conflicts with relational aggression. Preliminary research suggests that maltreated children exhibit significantly higher levels of relational aggression than their nonmaltreated peers (Rogosch & Cicchetti, 2005). However, relational aggression was included as part of a larger composite variable used to assess precursors of borderline personality features and was not of primary interest. Thus, the first goal of the present study was to investigate the links between maltreatment and both physical and relational aggression. We expected that maltreatment would emerge as an important predictor of both physical and relational aggression.

Gender as a moderator. The second goal of the present study was to examine whether maltreatment was associated with different forms of aggression for girls and boys. Within the maltreatment literature, the role of gender in the association between maltreatment and aggression has been relatively understudied. Due to the challenges inherent in this work, researchers have included samples of only one gender, used gender as a main effect variable, or been unable to examine the potential moderating effects of gender due to small samples (e.g., Calverley, Fischer, & Ayoub, 1994; Kitzmann, Gaylord, Holt, & Kenny, 2003; MacKinnon-Lewis et al., 1994; Trickett, McBride-Chang, & Putnam, 1994; Wolfe, Crooks, Lee, McIntyre-Smith, & Jaffe, 2003). Even when gender has been examined as a potential moderator, few investigations have found significant interactions between gender and maltreatment in the prediction of externalizing difficulties (Dodge, Pettit, & Bates, 1994; Sternberg et al., 2006). However, there are at least two reasons to expect that gender would moderate the relation between maltreatment and aggression using a gender-informed approach.

First, children at risk for aggressive behaviors due to experiences of maltreatment are likely to engage in gender-typical conduct when aggressive (i.e., relational aggression for girls, physical aggression for boys). Particularly during the early and middle childhood periods, children play in gender-segregated groups and exhibit behaviors that are consistent with the social norms of their peers (Rose & Rudolf, 2006). Furthermore, girls, but not boys, exhibit relational aggression in response to physiological stress caused by interpersonal provocations (e.g., Murray-Close & Crick, 2007). Thus, maltreated children may be especially likely to employ aggressive behaviors typical of their same-sex peer groups.

Second, research suggests that boys and girls differ in the ways in which they make meaning of their experiences (e.g., Rose & Rudolf, 2006) and in the value they place on various aspects of their relationships (e.g., Buhrmester, 1990; Bukowski, Newcomb, & Hartup, 1996). This may also be the case with respect to experiences of abuse and/or neglect. For example, girls may be more likely than boys to focus on the relational aspects of the maltreating environment, such as love withdrawal or the betrayal of trust within the parent–child dyad. Compared to boys, girls are more likely to focus on and value intimacy, trust, and closeness in their relationships (Coyne et al., 2006; Crick et al., 2002; Rose & Rudolf, 2006; Zahn-Waxler, Crick, Shirtcliff, & Woods, 2006) and to report dissatisfaction, emotional distress, and relational aggression when their relational needs are threatened (Crick et al., 2002; Galen & Underwood, 1997; Werner & Nixon, 2005). Therefore, because a focus on relational stressors is associated with heightened involvement in relational aggression (Crick et al., 2002; Murray-Close & Crick, 2007), we expected that maltreatment would predict especially high levels of relational aggression for girls.

In contrast, maltreated boys may be at particularly high risk for involvement in physical aggression. Boys tend to emphasize physical and instrumental competence in their social interactions with others (Bukowski et al., 1996; Rose & Rudolf, 2006) and are more likely to use physical aggression during instrumental conflict situations (Crick & Werner, 1998; Grotpeter & Crick, 1996). As such, maltreated boys may be particularly vulnerable to aspects of the maltreating environment that threaten their own or their loved ones' physical security such that they readily perceive and respond to such threats with physical aggression (Cummings et al., 1994; Dodge et al., 1990).

In sum, experiences of maltreatment may lead to different behavioral problems in boys and girls. We hypothesized that the effects of maltreatment on physical and relational aggression would be contingent on the gender of the child, such that maltreatment would predict higher levels of physical aggression among boys and higher levels of relational aggression among girls.

Gender, maltreatment subtypes, and aggression. The final goal of this study was to better understand the associations between specific maltreatment subtypes and aggression using a gender-informed approach. We expected that subtypes of abuse would differentially predict physical and relational aggression. Specifically, we hypothesized that physical abuse would be associated with physical forms of aggression. Physical abuse has been shown to disrupt SIP and emotional regulation, which in turn have been associated with physical aggression among physically abused children (Dodge, Pettit, Bates, & Valente, 1995; Klimes-Dougan & Kistner, 1990; Rogosch et al., 1995; Teisl & Cicchetti, 2008). In contrast, although there is a paucity of research in this area, we expected sexual abuse to be associated with relational aggression because sexual abuse violates aspects of relationships, such as trust and intimacy, which are known to be associated with relationally aggressive behavior patterns (Crick et al., 2002; Howes, Cicchetti, Toth, & Rogosch, 2000).

Specific maltreatment subtypes may be especially important in differentially predicting boys' and girls' aggressive conduct. Findings from the Third National Incidence Study indicate that boys are more likely to sustain physical injuries as the result of maltreatment (Sedlak & Broadhurst, 1996). Furthermore, some research suggests that physical abuse may have more deleterious effects on boys than on girls (e.g., Jaffe, Wolfe, Wilson, & Zak, 1986) and that physically abused boys are more likely than girls to exhibit physical aggression (Cummings et al., 1994). Thus, we hypothesized that physical abuse would predict higher levels of physical aggression, particularly for boys.

In contrast, girls are three times more likely than boys to be sexually abused (Sedlak & Broadhurst, 1996), and some researchers have proposed that sexual abuse may be a particularly salient risk factor for girls (e.g., Feiring, Taska, & Lewis, 1999). Girls are not only more likely than boys to experience sexual abuse and, when aggressive, use relationally aggressive behaviors, but compared to boys, they are also more likely to focus on and value intimacy and closeness in their relationships, aspects that become toxic and confusing where sexual abuse occurs (e.g., Howes et al., 2000; Kendall-Tackett, Williams, & Finkelhor, 1993). When needs of relational security are threatened, girls are more likely than boys to show signs of distress and to respond with relational aggression. Furthermore, both sexually abused and relationally aggressive girls display negative self-views and feel more guilt and regret in relation to their interactions with others (e.g., Calverley et al., 1994; Feiring et al., 1999; Moretti, Holland, & McKay, 2001). For these reasons, we hypothesized that sexual abuse would be associated with higher levels of relational aggression, particularly for girls.

Method

Participants

A total of 410 children who attended a weeklong day camp research program for inner-city youth participated in the present study. Demographic characteristics for the sample are shown in Table 1. Participants included 211 (123 boys) maltreated and 199 (90 boys) nonmaltreated children ranging in age from 6 years 1 month to 12 years 11 months (average age was 9.93 years). Maltreated and nonmaltreated children did not differ significantly on age, $F(1, 408) = 0.87$, *ns*. The majority of children were of an ethnic minority (83.7%). Fifty-six percent of participants were Black, 16.3% were White, 11.2% were Latino/Hispanic (non-Black), 13.8% were biracial, 0.7% were American Indian, and 2.2% were of other ethnicities. Ethnicity was significantly associated with maltreatment, $\chi^2(5, n = 410) = 11.83, p < .05$. Follow-up analyses sequentially comparing each ethnic group

Table 1
Demographic Characteristics of Sample by Gender and Maltreatment Status

		Gender		Maltreatment status	
Variable	Whole sample $N = 410$ (100%)	Boys $n = 213$ (52%)	Girls $n = 197$ (48%)	Maltreated $n = 211$ (51.5%)	Nonmaltreated $n = 199$ (48.5%)
Age	9.93 (1.81)	9.85 (1.86)	10.00 (1.75)	9.97 (1.86)	9.88 (1.75)
White	67 (16.34)	28 (6.83)	39 (9.51)	40 (9.76)	27 (6.59)
Minority	343 (83.67)	185 (45.12)	158 (38.54)	171 (41.71)	172 (41.95)
Black	228 (55.61)	120 (29.27)	108 (26.34)	106 (25.85)	122 (29.76)
Latino/Hispanic	46 (11.22)	29 (7.07)	17 (4.15)	21 (5.12)	25 (6.10)
Biracial	57 (13.90)	31 (7.56)	26 (6.34)	39 (9.51)	18 (4.39)

Other	9 (2.20)	2 (0.49)	7 (1.71)	4 (0.98)	5 (1.22)
Boys	213 (52)			123 (30.00)	90 (21.95)
Girls	197 (48)			88 (21.46)	109 (26.59)

Note. Values for age = mean age (*SD*) in years. All other values indicate frequencies (percentages of whole sample).

against the remainder of the sample revealed a higher than expected level of maltreatment among biracial participants, $\chi^2(1, n = 410) = 7.62, p < .01$, and a lower than expected level of maltreatment among African American participants, $\chi^2(1, n = 410) = 5.08, p < .05$.

Participants in both maltreatment and comparison groups were from low-income, demographically similar backgrounds based on Hollingshead's (1975) four-factor index of social status (accounting for gender, occupation, education, and family configuration). All children were living with their biological mothers, most of whom were single parents. Maltreated children were recruited based on a history of child maltreatment as reported through the Monroe County (New York) Department of Social Services (DSS). Due to the need to protect the rights of confidentiality, families were initially approached by a DSS staff member. This DSS liaison met with a random sample of families on the DSS rosters who had children aged 6–12 years. The liaison explained the project to the mother of a target-age child and asked if she was willing to participate. The DSS liaison was careful to stress the voluntary nature of the project to avoid feelings of coercion and assured the mother that her refusal to participate would in no way affect her or her family's status with DSS or access to related services. Once mothers expressed an interest, the DSS liaison asked the mother sign a release form indicating her willingness to be contacted by research staff. Following a similar procedure, nonmaltreated participants were recruited from a random sample of families who received Temporary Assistance to Needy Families. Prior to enrolling in the study, mothers of both maltreated and nonmaltreated children provided written consent to allow trained project staff to examine any existing DSS records.

Several safeguards were used to determine the maltreatment status of the maltreated and nonmaltreated comparison groups. First, trained staff (doctoral students from Clinical and Social Sciences and clinical psychologists) carefully examined family records at the local Child Protection and Preventive Services to confirm the presence or absence of abuse within the family. Second, mothers of nonmaltreated children were interviewed to screen for maltreatment (see Cicchetti, Toth, & Manly, 2003). All maltreated children in the present study had a documented history of family abuse with Child Protection and Preventive Services at the DSS resulting in services through the agency; in contrast, nonmaltreated children had no history of abuse in these records or indicators of maltreatment based on interviews.

Specific maltreatment experiences were coded from DSS records using the Maltreatment Classification System (MCS; Barnett, Manly, & Cicchetti, 1993). Previous studies indicate that the MCS is both reliable and valid in classifying maltreatment subtypes (e.g., Bolger & Patterson, 2001; Manly, 2005). Consistent with this research, adequate reliability was obtained for each maltreatment subtype (kappas for physical, sexual, and emotional abuse were 1.00 and .90 for neglect).

The presence of sexual, physical, emotional abuse, and/or neglect in each family was assessed using criteria outlined by Barnett et al. (1993) based on the MCS operational criteria for maltreatment subtypes. The primary emphasis of the MCS subtypes definitions is on the parental behaviors that potentially result in psychological or physical harm to the child. *Sexual abuse* involves any attempted or actual sexual contact between a child and a caregiver for the caregiver's satisfaction or financial benefit. *Physical abuse* is the infliction of physical injury on a child other than by accident, such as beatings that result in bruises, choking, or burning a child. *Emotional maltreatment* occurs when caregivers prevent children from obtaining needed psychological safety and security, acceptance, self-esteem, and age-appropriate autonomy (e.g., ridiculing the child, abandoning the child, exposing the child to violence). *Neglect* is the failure to provide for children's basic physical needs and supervision or moral–legal or educational neglect. Neglect may result in lack of adequate food, shelter, or clothing or cause harm or potential harm from lack of supervision. Child protection services (CPS) narratives could include information that pertained to several forms of maltreatment. In such cases, information was scrutinized to determine the ways in which the parent's behavior threatened the child. For example, parent alcohol use may have resulted in the inability to provide adequate food or shelter and would thus be considered neglect, or it could have resulted in physically violent behaviors toward the child while under the influence and therefore be considered physical abuse. The number of children who experienced each subtype based on these definitions is provided in Table 2.

Design and Procedure

Participants attended a weeklong summer day camp for inner-city children (for details of this setting, see Cicchetti & Manly, 1990). During the summer camp, children were assigned to groups of approximately eight ($M = 7.57$, $SD = 1.57$) same-sex and same-age peers. Half of the members in each group were maltreated and half were nonmaltreated. Each group was led by three camp counselors who were unaware of participants' maltreatment status or

Table 2
*Frequencies and Percentages of Maltreated Children by Maltreatment Subtype (*N *= 410)*

	Maltreatment subtype			
	Sexual abuse, *n* (%)	Physical abuse, *n* (%)	Neglect, *n* (%)	Emotional maltreatment, *n* (%)
Presence (1)	31 (7.6)	104 (25.4)	169 (41.2)	147 (35.9)
Absence (0)	379 (92.4)	306 (74.6)	241 (58.8)	263 (64.1)

the study hypotheses. During the summer camp, children participated in a number of recreational and research activities, including the completion of instruments assessing the social behaviors of the peers in their group. In addition, camp counselors completed measures assessing the children's behavior in their group following each camp session.

Measures

Given the limitations of many single measures of aggressive conduct, children's physically and relationally aggressive behaviors were assessed using a multi-informant approach.

Peer ratings of aggression. First, children completed ratings of their peers' physically and relationally aggressive behaviors. Children were provided with one item depicting a physically aggressive child ("starts fights, says mean things, pushes or hits others") and one item depicting a relationally aggressive child ("when s/he is mad at someone, refuses to play or talk to the person, will try to get others not to like the person, will spread rumors or talk behind the person's back") and asked to rate how true each item was of each peer in their group on a scale of 0 (*not true*) to 2 (*very true*). The rating scores received from each peer in the group were averaged to yield an overall peer rating of physical aggression and relational aggression for each child.

Peer nominations of aggression. For the second measure of aggression, participants completed a peer nomination procedure. Group participation rates ranged from 75% to 100% ($M = 95\%$, $SD = 7\%$). Each child was asked to nominate one child in their group who fit the description of a physically aggressive child (this child "starts fights. He/she says mean things to other kids, or pushes them, or hits them") and a relationally aggressive child (this child, "when he/she is mad at someone, will refuse to play or talk to the person, will try to get others not to like the person, will spread rumors or talk behind the person's back"). The nominations received for each item were summed, standardized within group, and then standardized across all camp participants to yield total relational aggression and total physical aggression peer nomination scores.

Counselor report of aggression. The third measure of children's aggression was an instrument developed in previous research with teachers (Crick, 1996) and adapted to be used by camp counselors (Shields & Cicchetti, 2001). Counselors were provided with statements about physically aggressive behaviors (four items; e.g., "This child hits or kicks peers"), relationally aggressive behaviors (five items; e.g., "When mad at a peer, this child ignores the peer or stops talking to the peer"), and prosocial behaviors (four items; positively toned filler items) and asked to rate how true each statement was of the target child on a scale from 1 (*never true*) to 5 (*almost always true*). Each participating child was rated by two of the three counselors for their group. Subscales were computed by summing across physical and relational aggression items, respectively. These subscales were then averaged across counselors, yielding overall physical and relational aggression scores. Evidence for the validity of this measure has been demonstrated in previous research (Crick, 1996; Shields & Cicchetti, 2001). Cronbach's alpha demonstrated high reliability of the measures for this sample, with $\alpha = .97$ for physical aggression and $\alpha = .90$ for relational aggression.

Composite aggression scores. Composite physical and relational aggression scores were computed for each participant based on his or her counselor report, peer nomination, and peer ratings of aggression. Relational aggression scores and physical aggression scores from each method were transformed to z scores, summed, and then standardized across camp participants to yield a composite relational aggression score and a composite physical aggression score, respectively. The internal consistencies of the composite aggression scales were acceptable, with $\alpha = .70$ for relational aggression and $\alpha = .83$ for physical aggression. In addition, confirmatory factor analyses (CFA) using Mplus were conducted to examine the latent structure of the composite aggression variables. Results of the CFA indicated good fit with counselor reports, peer nominations, and peer ratings loading onto physical and relational aggression, respectively, and correlated residuals across informant types (comparative fit index [CFI] = 1.0, standardized root mean squared residual [SRMR] = .01). Moreover, all indicators exhibited large and significant loadings on their factor (*M* loading = 0.73, range = 0.50 – 0.97). Finally, nested model comparisons indicated that the model with separate physical and relational aggression factors provided significantly better fit than the model with one latent aggression factor, $\chi^2(1) = 8.34, p < .01$. These findings provide support for the validity of the composite physical and relational aggression factors in the present sample.

Means and standard deviations for each aggression measure are listed in Table 3. Peer ratings, peer nominations, and counselor reports of physical and relational aggression were significantly and moderately correlated (see Table 4). In addition, composite aggression scores for physical and relational aggression were strongly and significantly related to peer ratings, nominations, and counselor reports, with *r*s ranging from .83 to .91 and .76 to .82, respectively. Composite aggression scores were used in all analyses.

Table 4

Correlations Among Relational and Physical Aggression Measures (N = 410)

Variable	Correlations 1	2	3	4	5	6
1. Relational aggression—peer ratings	—					
2. Relational aggression—peer nominations	.53	—

4. Physical aggression—peer ratings	.79	.59	.45	—		
5. Physical aggression—peer nominations	.54	.71	.35	.65	—	
6. Physical aggression—counselor reports	.60	.44	.50	.72	.51	—

Note. All correlations are statistically significant at $p < .001$.

Results

Descriptive information and correlations among age, race, gender, maltreatment, and aggression variables are presented in Table 5.

Maltreatment Status and Aggression

The first two goals of this study were to assess whether maltreatment status was associated with physical and relational aggression and to examine whether this association differed for boys and girls. We predicted that maltreatment would be associated with both physical and relational aggression. Furthermore, we expected that this relation would be moderated by gender, such that maltreatment would be more strongly related to physical aggression for boys and relational aggression for girls. Correlations between maltreatment status and aggression indicated that experiencing maltreatment was positively correlated with physical (phi = .19, $p < .001$) and relational (phi = .17, $p < .001$) aggression. To examine the role of gender in these relations, a series of

$^{\dagger}p < .10$. $^{*}p < .05$. $^{**}p < .01$. $^{***}p < .001$.

analyses of covariance (ANCOVAs) were conducted. Given the overlap between physical and relational aggression ($r = .81$, $p < .001$, in the present sample), the nonfocal form of aggression was entered as a covariate in all analyses. Age and ethnicity were also entered as covariates to control for the potential effects on aggression (Archer & Coyne, 2005; Cillessen & Mayeux, 2004). For these analyses, a four-category ethnicity variable was created representing Black, White, biracial, and other groups.

First, a 2 (maltreatment status: nonmaltreated vs. maltreated) × 2 (gender) ANCOVA was conducted with physical aggression serving as the dependent variable and age, ethnicity, and relational aggression entered as the covariates. As depicted in Table 6, the results indicated significant effects of ethnicity and relational aggression in predicting children's physically aggressive behaviors. Black children ($M = 0.16$, $SD = 1.05$) were significantly more likely to exhibit physical aggression than White children ($M = -0.28$, $SD = 0.72$), $p < .01$, and children of other ethnicities ($M = -0.38$, $SD = 0.78$), $p < .01$. Black and biracial children ($M = 0.08$, $SD = 1.12$) did not differ significantly on physical aggression. In addition, the effect for gender was significant, with boys exhibiting greater levels of physical aggression ($M = 0.14$, $SD = 1.10$) than girls ($M = -0.17$, $SD = 0.82$) based on the estimated marginal means. Finally, the Gender × Maltreatment Status interaction was significant. Follow-up planned comparisons revealed that maltreated boys ($M = 0.24$, $SD = 1.15$) were more physically aggressive than nonmaltreated boys ($M = 0.04$, $SD = 0.98$), $p < .05$; nonmaltreated girls ($M = -0.16$, $SD = 0.67$), $p < .001$; and maltreated girls ($M = -0.19$, $SD = 0.95$), $p < .001$.

Second, a 2 (maltreatment status) × 2 (gender) ANCOVA was conducted with relational aggression serving as the dependent variable and age, ethnicity, and physical aggression entered as the covariates. The results, shown in Table 7, indicated that physical aggression was a significant predictor of relational aggression. In addition, the effect for gender was significant, with girls displaying greater levels of relational aggression ($M = 0.11$, $SD = 1.02$) than boys ($M = -0.09$, $SD = 0.97$) based on the estimated marginal means. Finally, the Gender × Maltreatment Status interaction was significant. Planned comparisons indicated that maltreated girls ($M = 0.20$, $SD = 1.13$) were more relationally aggressive than nonmaltreated girls ($M = 0.03$, $SD = 0.89$), $p < .05$; maltreated boys ($M = -0.13$, $SD = 0.98$), $p < .01$; and nonmaltreated boys ($M = -0.05$, $SD = 0.94$), $p < .001$.

Subtypes of Maltreatment and Aggression

The third goal of the present study was to examine the association between subtypes of maltreatment and aggression and to investigate whether this relation differed for boys and girls. We expected that physical abuse would be associated with physical aggression, particularly for boys. In addition, we expected that sexual abuse would predict relational aggression, particularly for girls.

To examine the associations between maltreatment subtypes, gender, and physical and relational aggression, a series of hierarchical multiple regression analyses were computed. For each regression, age, ethnicity, and the nonfocal form of aggression were entered into Step 1. Ethnicity was dummy coded into several dichotomous variables representing "Black" (0 = *non-Black*, 1 = *Black*), "White" (0 = *non-White*, 1 = *White*), and "biracial" (0 = *nonbiracial*, 1 = *biracial*) groups, with "other" serving as the reference group. Maltreatment subtypes were then entered into Step 2. This allowed us to examine the unique effects of each subtype while controlling for the potential effects of experiencing other forms of maltreatment. Maltreatment subtypes were dummy coded to assess the effects of each subtype (e.g., 0 = *not sexually abused*, 1 = *sexually abused*) on aggressive conduct. Finally, to

investigate the effects of gender and its potential moderating role in the relation between maltreatment subtypes and aggression, gender (0 = *male*, 1 = *female*) and each Subtype × Gender interaction term were entered into Step 3. Due to the high correlation between relational and physical aggression, multicollinearity diagnostics were examined. Tolerance levels (0.3–0.34), variance inflation factors (2.94–3.3), and the standard error of the regression coefficients (.03) were in acceptable ranges for all regression analyses. Follow-up hierarchical regression analyses were computed separately for boys and girls to break down significant or marginally significant interactions between subtype of abuse and gender. In these analyses, age, ethnicity, nonfocal form of aggression, and subtypes from nonsignificant interaction terms were entered into Step 1 and maltreatment subtypes from significant interactions were entered into Step 2.

Physical aggression. The results of the regression examining the role of maltreatment subtypes in children's physically aggressive behaviors are presented in Table 8. Thus, findings revealed that age, ethnicity, relational aggression, maltreatment subtypes, gender, and the interactions between maltreatment subtypes and gender accounted for a substantial amount of variance (70%) associated with physical aggression. As shown in Table 8, experiences of maltreatment significantly predicted children's involvement in physical aggression, even after controlling for age, ethnicity, and relational aggression. Tests of individual effects indicated that children who were physically abused had higher levels of physical aggression than those who were not physically abused. The addition of gender and the interaction terms in Step 3 resulted in a significant, albeit small (3%), increase in the model R^2 ($p < .001$). Tests of individual effects indicated that boys were more physically aggressive than girls. The Gender × Sexual Abuse interaction was marginally significant ($p = .08$). Due to the conservative nature of these analyses, exploratory follow-up hierarchical regressions were conducted separately for boys and girls. Findings revealed that sexual abuse was significantly associated with physical aggression for girls, such that girls who were sexually abused exhibited lower levels of physical aggression than nonsexually abused girls ($p < .01$).

Relational aggression. The results of the regression examining the role of maltreatment subtypes in children's relationally aggressive behaviors are presented in Table 9. The results indicated that age, ethnicity, physical aggression, maltreatment subtypes, gender, and the interaction between maltreatment subtypes and gender accounted for a substantial amount of variance (68%) in the prediction of relational aggression.

As shown in Table 9, gender and experiences of maltreatment significantly predicted children's involvement in relational aggression, even after controlling for age, ethnicity, and physical aggression. The addition of gender and the interaction terms in Step 3 resulted in a significant, although small (2%), increase in the model R^2 ($p < .01$). In addition, the Gender × Sexual Abuse interaction was significant. Follow-up hierarchical regressions were conducted separately for boys and girls. Findings revealed that, as expected, sexual abuse was significantly associated with relational aggression for girls ($p < .01$) but not for boys.

Discussion

This investigation brings together three areas important to the study of development and advances our knowledge in a relatively understudied area of research, namely, maltreatment, gender, and relational aggression. Our goal in designing this study was to examine the relations between maltreatment and aggression using a gender-informed approach. In our models, we examined not only the associations between children's experiences of maltreatment and aggression but also the relations between specific subtypes of maltreatment and forms of aggression that are salient to both boys and girls (Crick et al., 2006; Feiring et al., 1999). Unlike prior research on maltreatment and aggression (e.g., Dodge et al., 1994; MacKinnon-Lewis et al., 1994; Shields & Cicchetti, 2001), we were able to discern the unique effects of gender and subtypes within a developmental perspective by including gender-relevant independent and dependent variables while controlling for nonfocal forms of aggression in these models.

The first goal of this study was to examine the association between childhood maltreatment and peer aggression by investigating whether children's experiences of maltreatment would significantly predict both physical and relational forms of aggression. Although maltreatment was positively associated with greater levels of both forms of aggression, our findings indicated that we must examine the moderating role of gender in order to understand the associations between maltreatment and aggression. This is consistent with the second goal of this investigation. In contrast to previous studies (e.g., Sternberg et al., 2006), we found that gender moderated these relations. As expected, whereas maltreated boys exhibited higher levels of physical aggression than

maltreated girls and nonmaltreated children, maltreated girls displayed higher levels of relational aggression than all other groups. The associations between maltreatment and aggression for boys and girls may be explained in part by children's tendency to use forms of aggression that are consistent with the norms of their peer cultures, particularly during middle childhood. For example, Rose and Rudolf (2006) argue that children are more likely to exhibit sex-linked outcomes of adjustment (in this case, physical aggression among boys and relational aggression among girls) to the degree that they interact with same-sex peers. This would be particularly true in the current study where most participants were in middle childhood and all interacted in groups of same-sex peers.

Moreover, the unique associations (i.e., significant interactions) between maltreatment and relational and physical aggression for boys and girls indicate that girls and boys not only differ in their expression of aggression but may also internalize the experience of maltreatment in different ways. It is possible that boys and girls attend to and incorporate different aspects of their relationships with caregivers in making meaning of their relationships with peers. For example, maltreated children often display attentional as well as attributional biases that affect how they respond to others, understand their relationships with caregivers, and avoid or attend to threatening stimuli (Cicchetti & Curtis, 2005; Klimes-Dougan & Kistner, 1990; MacKinnon-Lewis et al., 1994; Rogosch et al., 1995; Shields et al., 2001). Future research should explore the ways in which maltreated boys and girls attend to various aspects of the caregiving system and how specific patterns of individual differences in attentional and attributional processes may influence peer interactions.

The third goal of this study was to extend current knowledge about the influence of subtypes of maltreatment in understanding the developmental trajectories of physical and relational aggression for both boys and girls. To address this issue, we conducted several hierarchical multiple regressions that enabled us to first assess the unique contributions of maltreatment subtypes in the prediction of physical and relational aggression and then to examine the contribution of gender and its potential moderating role on these relations. Findings revealed that maltreatment subtypes contributed significantly to the prediction of physical aggression above and beyond that accounted for by age, ethnicity, and relational aggression. As expected, physical abuse emerged as a stronger predictor of children's physical aggression than the other maltreatment subtypes examined. These findings are consistent with the view that physical abuse may initiate a pathway to externalizing difficulties, particularly physical aggression (e.g., Dodge et al., 1994), whereas experiences of neglect or sexual abuse may foster different developmental outcomes (Bolger & Patterson, 2001; Kim & Cicchetti, 2006). It is also possible that in order to understand how other maltreatment subtypes, such as sexual abuse, affect children's physical aggression, moderating variables, such as gender, need to be examined. Indeed, the findings revealed that the inclusion of gender and the Gender × Maltreatment Subtype interaction terms added a small but significant amount of variance in the prediction of physical aggression. Follow-up analyses revealed that sexual abuse was associated with lower levels of physical aggression for girls only.

Consistent with this view, results also indicated that gender and its moderating role must be considered when examining the associations between maltreatment subtypes and relational aggression. As hypothesized, findings revealed that sexual abuse was associated with higher levels of relational aggression for girls only, even after statistically controlling for the effects of age, ethnicity, and physical aggression. In contrast, without gender as a moderator, maltreatment subtypes did not contribute to the prediction of relational aggression.

Taken together, the findings are consistent with a gender-informed model of development and developmental psychopathology (Crick & Zahn-Waxler, 2003; Moffit & Caspi, 2001; Silverthorn & Frick, 1999; Zahn-Waxler et al., 2006) and suggest that we must consider specific maltreatment experiences, especially physical and sexual abuse, within the context of gender when predicting physical and relational aggression.

This investigation addressed several shortcomings present within the maltreatment and aggression literatures. First, unlike many prior studies (Kitzmann et al., 2003; Trickett et al., 1994; Wolfe et al., 2003), this investigation included a large sample of maltreated and nonmaltreated children, composed of both boys and girls, so that the moderating role of gender in the association between maltreatment subtype and aggression could be assessed. In contrast to other studies using gender as a control variable (e.g., Bolger & Patterson, 2000), we specifically examined the moderating effects of gender on the relation between maltreatment and aggression. Furthermore, the sample included demographically similar maltreatment and comparison groups, which controlled for the potentially confounding effects of environmental stressors on children's aggression, such as the risks associated with living in poverty. Finally, by investigating children's use of relational aggression among socioeconomically disadvantaged children, our findings add to the emergent literature on children's use of relational aggression among low-socioeconomic-status samples (Bonica, Arnold, Fisher, Zeljo, & Yershova, 2003; Sullivan, Farrell, & Kliewer, 2006) and call into question the notion often perpetuated among the popular press that relational aggression is predominately a problem of middle- and upper-class children (for a review, see Crick, 2007).

Implications, Limitations, and Future Directions

The current findings have several implications for future research. First, research is needed to understand the mechanisms through which maltreatment and its various subtypes affect the development of physical and relational aggression among boys and girls. Future research should explore whether boys and girls attend to and incorporate particular aspects of maltreating relational systems in ways that lead to their reliance on relational and physical aggression with peers. Of particular investigative interest would be how sexually and physically maltreated girls and boys allocate and control (e.g., initiate, inhibit, disengage) their attention to real and perceived threats, particularly emotional cues from the environment. For example, attentional biases have been found among physically abused children, such that they overattend to, more readily detect, and demonstrate heightened psychophysiological reactivity to expressions of anger (e.g., Pollak & Sinha, 2002). It is possible that boys and girls may exhibit different patterns of attention and control to different features of emotional expressions. For example, sexually abused girls have difficulties controlling intrusive thoughts and report heightened hyperarousal relative to boys (Feiring et al., 1999). These gender differences may have important implications for the development of physical and relational aggression among maltreated boys and girls.

Another important avenue for future research is to examine the ways in which attentional and attributional processes affect the meanings children make of their abusive experiences and how these interpretations relate to their use of aggression. Such work will be especially important for understanding the links between sexual abuse and relational aggression among girls. For example, compared to nonmaltreated girls, sexually abused adolescent girls have more negative, constrictive, and dissociative descriptions of themselves in response to the emotional tone set by those with whom they interact (e.g., Calverley et al., 1994). Emerging evidence also suggests that negative self-perceptions are related to relationally aggressive behaviors among girls but not among boys (Moretti et al., 2001). This finding may be associated with girls' tendency to feel guilt, regret, and loss of control following relationally aggressive events (Archer & Parker, 1994). Such feelings may begin during the sexually abusive experience, become internalized as distorted views of oneself in relation to others, and be expressed in the form of relational aggression, which in turn may bring about more guilt, regret, loss of control, and continued aggressive behaviors.

Given the disruption that maltreatment causes to children's ability to modulate their emotions and behaviors (Maughan & Cicchetti, 2002; Shields & Cicchetti, 2001), future work should also examine how emotional dysregulation relates to children's use of physical and relational aggression among maltreated and nonmaltreated children. Such difficulties have been shown to mediate the association between maltreatment and physical aggression (Shields et al., 2001), and given that relationally aggressive children have been shown to exhibit particularly heightened negative emotions and physiological reactivity in response to perceived relationship-oriented threats (Crick, 1995; Murray-Close & Crick, 2007), emotional dysregulation may serve as a vehicle through which maltreatment leads to children's use of relational aggression as well.

Finally, the current investigation represents a concurrent look at how relational and physical forms of aggression are related to maltreatment and how the development of these forms of aggression are highly contextualized (e.g., gender-specific) outcomes of an individual's interactions with his or her environments. However, replication research is needed. In addition, researchers should conduct longitudinal studies that explore the dynamic transactions within, as well as across, specific ecologies (e.g., family, peer, school) to better understand the links between maltreatment, aggression, and gender.

Conclusions

The findings from this study extend our current knowledge and have important implications for theory and research. This investigation represents the first study to specifically examine associations between maltreatment and relational aggression. Although the past decade has witnessed an increased focus on children's experience of relational aggression, few studies have investigated etiologic underpinnings of relational aggression or relevant familial risk factors associated with the development of relational aggression. This study adds to existing research by demonstrating that violent and relationally toxic maltreating family systems (often characterized by ambivalence, avoidance, enmeshment, and/or disorganization) affect not only the extent to which children exhibit physical aggression but also the degree to which they relationally manipulate their peers. This view is consistent with the second major contribution of this work. In this initial attempt to apply a gender-informed approach to the study of maltreatment and aggression, the findings suggest that we need to investigate the patterns of interactions between specific familial risk factors and aggression for both boys and girls. Indeed, our findings indicate that physical abuse may initiate a pathway to physically aggressive behaviors, whereas the developmental pathway for girls' aggression may be best understood when considering their sexual abuse histories and use of relational forms of aggression.

Neural Processing of Eye Gaze and Threat-Related Emotional Facial Expressions in Infancy

Stefanie Hoehl

Combined with emotional expressions, eye gaze can provide essential information to indicate threat in the environment. The current study assessed the effects of eye gaze direction on infants' neural processing of fearful and angry faces. Event-related potentials were recorded from thirteen 7-month-old infants. Two face-sensitive posterior components, the N290 and P400, as well as a frontocentral negative component (Nc), indicating attentional arousal, were sensitive to eye gaze direction and emotion. A larger Nc was observed for angry faces with direct compared to averted eye gaze. Fearful faces elicited a larger N290 than angry faces, whereas angry faces elicited a more prominent P400 regardless of eye gaze direction. The findings are discussed in terms of early social cognitive and neural development.

Stimuli that indicate threat automatically capture attention and elicit fear (Öhmann, 2005). Attention is biased toward emotionally salient stimuli, especially emotional facial expressions, which possess a threat-related value, like angry and fearful faces (Vuilleumier, 2002). In adults, the neural processing of emotional facial expressions is affected by eye gaze direction, that is, whether eye gaze is directed at the observer or averted from the observer (Adams, Heather, Baird, Ambady, & Kleck, 2003; Sato, Yoshikawa, Kochiyama, & Matsumura, 2004). For instance, an angry face with eye gaze directed at the perceiver is more threatening than an angry face with eye gaze averted to the side. When faced with potential threat or when encountering an ambiguous situation, one essential reaction is to turn toward other people and evaluate their emotional expressions. Others' behavior and emotional expressions help to guide our own behavior, especially in ambiguous or potentially dangerous situations (e.g., Latané & Darley, 1970; Prentice & Miller, 1996). However, the developmental trajectory that leads to the highly efficient social threat detection system in human adults has only been investigated in parts.

Neonates already differentiate between direct and averted eye gaze and prefer to look at a face with the eyes directed toward them (Farroni, Csibra, Simion, & Johnson, 2002). By the age of 3 months, infants are able to follow other's eye gaze (D'Entremont, Hains, & Muir, 1997). Increasing empirical evidence suggests that young infants use the eye gaze of adults to shift their attention in the direction of socially relevant information (Hood, Willen, & Driver, 1998; Reid & Striano, 2005; Reid, Striano, Kaufman, & Johnson, 2004). Eye gaze detection is a very basic mechanism that can be observed very early in human ontogeny and that is also phylogenetically very old. It can be found even in nonmammalian species such as snakes and chickens (Emery, 2000). Primates use eye gaze to communicate with others, for instance, to express emotional states or to attract others' attention toward objects in their environment (Call, Hare, & Tomasello, 1995; Keating & Keating, 1982). It has been suggested that the ability to detect eye gaze direction has evolved in order to detect threat from potential predators (Haxby, Hoffmann, & Gobbini, 2002).

Infants are also sensitive to emotional expressions in face and voice from a very early age onward (see, e.g., de Haan & Nelson, 1998; Leppänen & Nelson, 2006; Walker-Andrews, 1997, for a review). For instance, by 6–7 months, infants discriminate most emotional expression pairings in habituation paradigms (de Haan & Nelson, 1998). Even though young infants possess remarkable skills regarding the discrimination and categorization of emotional facial

expressions, there is converging evidence that early social and emotional experience strongly affects the development of emotion processing (e.g., Parker, Nelson, & The Bucharest Early Intervention Project Core Group, 2005; Pollak, Cicchetti, Hornung, & Reed, 2000). As concluded by Leppänen and Nelson (2006), this indicates that the neural emotion processing system may not be innately specified but rather may become fine-tuned to the processing of emotional expressions with growing social experience.

Infants are especially susceptible to others' emotional feedback in ambiguous or disturbing situations. By 12 months, infants show social referencing; that is, they turn toward their caregivers and use referential emotional cues from caregivers to adjust their behavior accordingly (Moses, Baldwin, Rosicky, & Tidball, 2001; Sorce, Emde, Campos, & Klinnert, 1985). For instance, when placed on the edge of a visual cliff, that is, a Plexiglas surface covering an apparent depth, infants turn toward their caregivers to obtain information that disambiguates the apparently dangerous situation (see Feinman, Roberts, Hsieh, Sawyer, & Swanson, 1992, for a review). Facial and vocal expressions of emotion significantly affect infants' behavior when they are faced with a visual cliff (Sorce et al., 1985; Vaish & Striano, 2004). Infants cross the depth more often and also quicker when the mother directs joyful or interested expressions to them compared to angry or fearful expressions. In these studies, infants actively use emotional expressions provided by the caregiver to disambiguate the situation. However, it has to be noted that by using social referencing paradigms, it is often hard to distinguish between reactions to different emotions that share the same general value. For instance, infants may react in the same way to an angry and a fearful expression, both being negative in value, which makes it hard to draw conclusions on infants' discrimination between these expressions.

Despite the relevance of eye gaze detection and the perception of emotional facial expressions, little is known about how the developing human brain detects and responds to expressions of threat-related emotions in association with social referential cues. Studies on social referencing often require the infant to locomote or perform a certain action; therefore, mostly infants from the age of 12 months or older are tested (e.g., Sorce et al., 1985). This is why we know little about the emergence or precursors of social referencing in infants at younger ages.

In contrast to classic social referencing paradigms, event-related potential (ERP) measures do not require overt behavioral responses from the infant and may therefore be more sensitive measures of young infants' social cognitive skills (see also de Haan & Nelson, 1997). We conducted a visual ERP experiment to investigate the influence of eye gaze direction on the neural processing of negative emotional facial expressions. We tested 7-month-old infants because evidence from behavioral studies suggests that infants are able to discriminate and categorize angry and fearful facial expressions by that age (e.g., Schwartz, Izard, & Ansul, 1985; Serrano, Iglesias, & Leoches, 1992), though there is also an ERP study that did not show differential processing of fearful and angry facial expressions in 7-month-olds (Nelson & de Haan, 1996).

We focused our analyses on three components that have been most thoroughly investigated in infant face processing research: the N290, P400, and Nc. Both the early negative N290 component and the later occurring positive P400, component occur at posterior channel sites and are currently being discussed as potential precursors to the face-sensitive adult N170 (de Haan, Johnson, & Halit, 2003; Halit, Csibra, Volein, & Johnson, 2004). The N170 is related to structural encoding of physical information in faces (e.g., Bentin, Allison, Puce, Perez, & McCarthy, 1996) and is sensitive to the emotional expression in a face (Batty & Taylor, 2003). The adult N170 it is larger for emotionally significant compared to neutral faces and to biological motion compared to neutral control stimuli (e.g., Batty & Taylor, 2003; Puce & Perret, 2003). Functional similarities between the infant N290 and P400 on the one side and the adult N170 on the other side have been investigated in studies comparing the processing of faces to the processing of inverted faces, monkey faces, or visual noise (de Haan, Pascalis, & Johnson, 2002; Halit, de Haan, & Johnson, 2003; see de Haan et al., 2003, for a review).

In contrast to the adult N170, the infant N290 is also sensitive to eye gaze direction in 4-month-olds (Farroni et al., 2002). Specific responses of the N290 to different emotional facial expressions have not been found yet. However, Leppänen, Moulson, Vogel-Farley, and Nelson (2007) showed that the infant P400 is larger in response to fearful compared to happy or neutral facial expressions. Yet no study has investigated the effect of eye gaze direction in combination with fearful and angry facial expressions on the N290 and P400.

Another important component in the context of infant face processing is the midlatency negative central (Nc) component on frontocentral channels. The Nc has consistently been related to attentional orienting to salient stimuli (Courchesne, Ganz, & Norcia, 1981; Nelson, 1994), and its amplitude is closely associated with attention as measured by heart rate deceleration (Richards, 2003). In prior ERP studies, the Nc was sensitive to emotional expressions. For instance, Nelson and de Haan (1996) found an enhanced Nc in response to fearful compared to happy faces, indicating that 7-month-old infants allocated more attention toward fearful faces. The Nc was also found to discriminate between happy and angry faces (Grossmann, Striano, & Friederici, 2007) and between angry, neutral, and happy prosody (Grossmann, Striano, & Friederici, 2005).

Our intention was to investigate whether the face-sensitive components N290 and P400 as well as the Nc are affected by emotional facial expressions of fear and anger as a function of eye gaze direction.

Our prediction was that the more direct or obvious indicators of threat would elicit the higher attentional arousal and therefore the more prominent Nc on frontocentral channels. An angry face directing gaze at the perceiver is an immediate indicator of threat and potential aggression. A fearful face, in contrast, as an indicator of threat in the environment might be more threatening when averting gaze from the perceiver and thus potentially directing gaze at something threatening in the environment. Consistent with these considerations, behavioral studies with adults have shown that direct gaze facilitates processing of angry expressions and averted gaze facilitates processing of fearful expressions (Adams & Kleck, 2003). We therefore predict an enhanced Nc amplitude for angry faces with direct gaze and fearful faces with averted gaze compared to the other conditions.

We hypothesized that the P400 would be sensitive to emotional expression. In particular, we expected to find the larger responses to fearful compared to angry faces. In an ERP study by Batty and Taylor (2003) with adult subjects, the N170 was larger for fearful faces compared to the other basic emotions, including anger (see also Leppänen et al., 2007), though this finding could not be replicated with young children (Batty & Taylor, 2006).

Based on the findings by Farroni et al. (2002), we expected the N290 to be sensitive to gaze direction, with direct eye gaze eliciting the larger negative deflection. However, this hypothesis was only tentative because in the study by Farroni et al., a younger age group was tested and all faces were neutral.

Method

Participants

Participants were recruited from an existing database of families who had expressed interest in volunteering for research in infant development. Participants were White and of middle socioeconomic status. Thirteen infants (7 males and 6 females) were included in the final sample, with an average age of 7 months +/− 11 days. All infants were born full term (37 – 41 weeks) and were in the normal range for birth weight. Another 20 infants were tested but were excluded from the final sample as a result of fussiness ($n = 7$) or failing to reach the minimum requirements for adequate averaging of the ERP data ($n = 13$). This corresponds to the common dropout rate in infant ERP studies (e.g., Halit et al., 2004; Leppänen et al., 2007; Striano, Reid, & Hoehl, 2006). However, it has to be noted that the relatively high number of infants who failed to reach the minimum number of trials for averaging can likely be accounted for by the relatively high number of conditions and consequently required high number of stimulus presentations (see the Procedure subsection), which were very demanding for the infants in terms of sustaining attention and sitting still (see de Haan, 2007, on how the number of conditions are constrained in infant ERP research). To be included in the sample, an infant had to contribute at least 10 artifact-free trials per condition to their grand average, a criterion that is often used in infant ERP studies (Leppänen et al., 2007; Nelson & de Haan, 1996; Reid & Striano, 2005). For each of the conditions, the average number of trials included per infant was between 12.6 and 13.9 trials. The experiments were conducted with the understanding and the written consent of each participant's parent.

Stimuli

Stimulus material consisted of portrait photographs of one male and one female actor whose eyes were directed either to the front or to the left or to the right in a horizontal plane. In each of the four conditions, 50% of the pictures displayed each of the actors. In infant ERP studies most commonly only pictures from one or two different actors are presented to minimize the effects of differences in low-level psychophysiological properties between pictures on infants' neural responses. Original pictures were taken from the NimStim Face Stimulus Set (www.macbrain.org). Angry and fearful pictures were taken from both actors. Their irises were moved from the middle to the left and right corner of the eyes using Adobe Photoshop. Stimulus size was 17.5 × 22 cm.

Stimuli were rated by 20 adult subjects (12 females, mean age = 29.7 years). Participants were asked to identify the expressed emotion in a multiple-choice mode and to indicate to what degree the face signaled a direct threat for them on a 6-point scale. Expressed emotion was identified correctly in 93.8% of all trials for faces with direct eye gaze and 92.5% of all trials for faces with averted gaze, indicating that manipulation of the pupil did not affect recognition of emotional expression. Rating of threat as signaled by the face was mainly affected by a strong main effect of emotion, $F(19) = 23.07, p < .001$, indicating that angry faces were perceived as more threatening ($M = 2.96$, $SD = 0.31$) compared to fearful faces ($M = 1.41$, $SD = 0.16$) in general.

Procedure

Infants sat on their mother's lap in a dimly lit sound-attenuated and electrically shielded cabin at a viewing distance of 90 cm away from a 70 Hz 17-in. stimulus monitor. The experiment consisted of one block with 240 trials (containing 60 angry faces with direct eye gaze, 60 angry faces with averted eye gaze, 60 fearful faces with direct eye gaze, and 60 fearful faces with averted eye gaze). Stimulus presentation was controlled using the software ERTS (BeriSoft Corporation, Germany).

The four conditions were presented to the infant in a random order with the constraint that the same condition was not presented three times consecutively and that the number of presentations of each set of stimuli was balanced in every 16 trials. Each trial was preceded by a colorful attention attractor presented in the middle of the screen for 500 ms. Then, a stimulus picture was presented for 1,000 ms. After the presentation of every stimulus, the screen was blank for a random period of between 800 and 1,000 ms. The interstimulus interval (including the blank screen period and the fixation object) summed up to between 1,200 and 1,500 ms. If the infant became fussy or uninterested in the stimuli, the experimenter gave the infant a short break. During the break, the caregivers tried to reengage the infant if he or she got tired or bored or calm the infant if he or she got fussy. Sometimes caregiver and infant left the cabin for a couple of minutes. Then, the stimulus presentation and recording session were continued. The session ended when the infant's attention could no longer be attracted to the screen. Electroencephalogram (EEG) and electrooculogram (EOG) were recorded continuously, and the behavior of the infants was also video recorded throughout the session.

EEG Recording and Analyses

EEG was recorded continuously with Ag–AgCl electrodes from 19 scalp locations of the 10–20 system, referenced to the vertex (Cz), which were attached to a cap. Data were amplified via a Twente Medical Systems 32-channel REFA amplifier. Horizontal and vertical EOGs were recorded bipolarly. Sampling rate was set at 250 Hz. EEG data were rereferenced off-line to the mathematically combined linked mastoids. A band-pass filterwas set from 0.3 to 20 Hz.

The EEG recordings were segmented into epochs of waveform that comprised a 200-ms baseline featuring a colorful attention attractor and 1,000 ms of one static image featuring a face, as described earlier. For the elimination of electrical artifacts caused by eye and body movements, EEG data were rejected off-line whenever the standard deviation within a 200-ms gliding window exceeded 80 microvolts at EOG electrodes or 50 microvolts at any scalp electrode. Data were also visually edited off-line for artifacts and matched with the infant's recorded behavior. Only trials were included in which the infant had looked to the screen and displayed no eye movements on the video recording or on the EOG.

Initially, the grand average contained a very prominent early negative drift in one of the conditions (fearful–averted) starting directly after stimulus onset and lasting over the whole time course of the ERP on most of the channels. This drift could not be eliminated applying a baseline correction against mean voltage in the 200 ms period prior to stimulus onset. We thus decided to redo the analyses with a baseline correction against the mean voltage within the whole analyzed time window for all four conditions individually, which realigned the waveforms in a sufficient way, such that no unusual drifts were

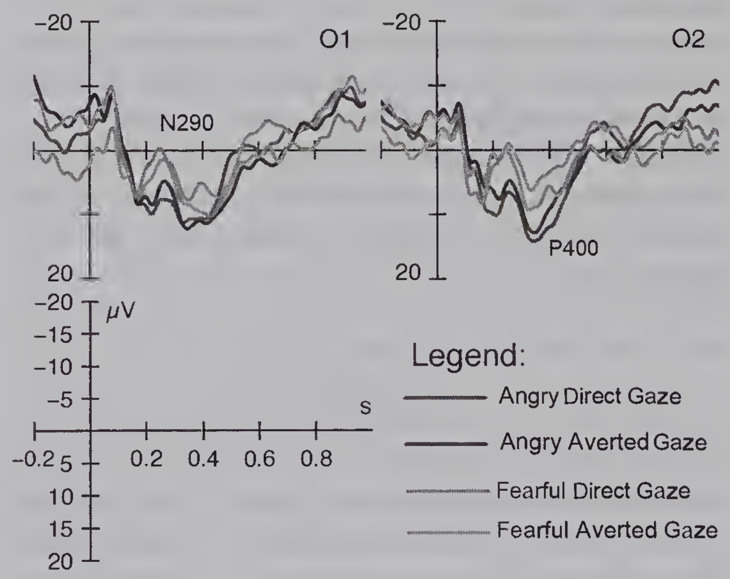

Figure 1. Grand average for all four conditions on occipital channels. Note that negative is plotted up in this figure. The N290 response is enhanced for fearful faces with direct and averted eye gaze (light gray lines) compared to angry faces with direct and averted eye gaze (dark gray and black lines). The P400 is more pronounced in conditions with angry facial expressions.

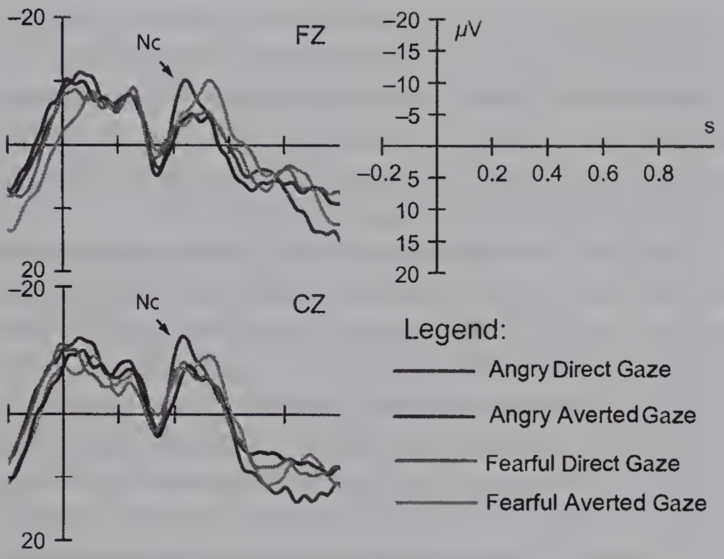

Figure 2. Grand average for all four conditions on frontocentral channels. Note that negative is plotted up in this figure. The Nc is larger for angry faces with direct eye gaze (dark gray lines) compared to angry faces with averted eye gaze (black lines). No similar effect was detected in the fearful face conditions.

evident in the final grand average (see Figures 1 and 2). Note that the same baseline correction was used for all four conditions.

For statistical analyses, three time windows were chosen to assess the effects of direct and averted eye gaze on infants' neural processing of angry and fearful faces. For the N290, minimal peak amplitude and latency were analyzed in an occipital channel group (O1 and O2) and on lateral parietal channels (P7 and P8) from 200 to 348 ms after stimulus onset. For the P400, maximal peak amplitude and latency were retrieved from 300 to 500 ms after stimulus onset on the same occipital and parietal channels. The Nc was investigated on a frontocentral channel group (FZ and CZ) from 348 to 600 ms after stimulus onset, assessing minimal peak amplitude and latency.

For all measures, a 2 × 2 repeated measures general linear model was performed with eye gaze (direct/averted) and emotion (angry/fearful) as independent factors.

Results

For the N290, a main effect of emotion was detected on occipital channels, $F(12) = 5.762$, $p = .03$. Minimal amplitude was smaller for fearful ($M = -5.85$ μV, $SD = 1.98$) compared to angry faces ($M = -1.49$ μV, $SD = 2.23$; see Figure 1). No other effects on amplitude or latency were found in this time range, and no effect was found on parietal channels.

For the P400, a main effect of emotion was found, $F(12) = 10.339$, $p = .007$. Maximal amplitude was larger for angry faces ($M = 21.10$ μV, $SD = 2.01$) than for fearful faces ($M = 15.37$ μV, $SD = 1.65$; see Figure 1). An additional peak-to-trough analysis was conducted to ensure that the effect found in this time window could not be accounted for by carryover effects due to the earlier N290 difference. Again, a significant main effect of emotion was found, $F(12) = 11.830$, $p = .005$. Maximal amplitude was larger for angry faces ($M = 19.64$ μV, $SD = 3.55$) than for fearful faces ($M = 9.52$ μV, $SD = 2.9$). No other effects on amplitude or latency were found in this time range, and no effect was found on parietal channels.

For the Nc, a significant Emotion × Eye Gaze interaction was found, $F(12) = 12.23$, $p = .004$. Post hoc t tests were applied to test our hypothesis that angry faces with direct eye gaze and fearful faces with averted eye gaze would elicit a larger Nc compared to the other conditions. In accordance to our expectations, infants reacted with an enhanced Nc to the angry faces with direct eye gaze ($M = -18.92$ μV, $SD = 7.12$) compared to angry faces with averted eye gaze ($M = -12.53$ μV, $SD = 5.11$), $t(12) = -3.62$, $p = .003$ (see Figure 2). For the fearful conditions, the Nc did not differ as a function of eye gaze direction. No other effects on amplitude or latency were found in this time range.

Additionally, we conducted statistic analyses on mean amplitude within the baseline on both channel groups because visual inspection of the ERPs indicated activity within the baseline, which can most probably be attributed to the colorful attention attractor that was presented prior to each stimulus and that was still presented during the baseline period. In particular, the negative deflection around stimulus onset on frontocentral channels may, according to its timing and topography, represent an Nc component in response to the central attractor. Though the attractor was the same for every stimulus picture, it may be that infants' reactions to the attractor were affected by the surrounding stimulus pictures. In other words, the presumably arousing angry and fearful face may have led to a more sensitive reaction and more pronounced Nc component in response to the attractor when compared to previous infant ERP studies. Variations in the baseline period on occipital channels may be related to the whole-window baseline correction that was used in the current study. A baseline correction to the mean voltage in the time window preceding stimulus onset usually realigns the waves in the baseline period on a similar level. This was not done in the present study. To still make sure that differences in later components are not affected by fluctuations in the prestimulus period, additional statistical analyses were conducted. Applying the same statistic analyses as described above, no significant effects on mean amplitude were found on frontocentral or occipital channels within the baseline period, indicating that the components that were explored in later time windows can be interpreted irrespective of fluctuations within the baseline.

Discussion

We conducted a visual ERP experiment with 7-month-old infants to investigate the effects of eye gaze and negative emotional expressions on the neural processing of unfamiliar faces. Differential processing of threat-related emotional expressions and eye gaze could be shown in several well-known components of the infant ERP.

When faces with angry expressions were presented with eye gaze directed at the infants attentional arousal was enhanced, as indicated by a larger Nc, compared to angry faces with averted eye gaze. No similar effect was found for fearful faces with direct or averted eye gaze. Our finding is in accordance with a previous ERP study in which 4-month-old infants showed enhanced neural processing of angry faces with direct eye gaze compared to averted eye gaze (Striano, Kopp, Grossmann, & Reid, 2006). An angry face that directs eye gaze at the perceiver is a clear signal for potential threat. Presumably, infants are already sensitive to the relevant social signals, which indicate threat in a social interaction even if only static two-dimensional images are presented. This highlights the social relevance and emotional valence of angry faces with direct eye contact already very early in ontogeny. However, alternative explanations should be taken into consideration. It may be that angry faces with direct eye gaze are merely less familiar to the infant compared to the other conditions. If that was the case, it may be that it was mainly the novelty of stimuli in this condition that elicited an enhanced Nc. It is known that mothers' expression of anger toward their infants does not increase until infants start to locomote (Campos et al., 2000). Experience and familiarity with emotional expressions are important factors that determine infants' discrimination and categorization abilities (Ludemann & Nelson, 1988) and probably affect the neural processing of emotional facial expressions (Parker et al., 2005). However, fearful faces with direct eye gaze should be no less familiar to the infants than angry faces. Still, the amplitude of the Nc was not enhanced for the fearful faces with direct eye gaze. Unfortunately, we have not tested infants' a priori familiarity with emotional facial expressions; therefore, a familiarity effect cannot be ruled out.

Importantly, our findings demonstrate that it was not direct eye gaze per se that elicited an enhanced Nc, as direct eye contact in association with a fearful expression did not have the same effect as in the context of an angry face.

In addition, differences in the face-sensitive posterior components N290 and P400 were assessed. In accordance with results from a previous ERP study with adults (Batty & Taylor, 2003), the N290 was significantly larger for fearful faces compared to angry faces, regardless of eye gaze direction. This main effect of emotion on amplitude of the N290 was evident on central occipital channels (O1 and O2) and not on more lateral channel sites (P7 and P8), as found in the study by Batty and Taylor (2003). As reviewed by de Haan et al. (2003), the infant N290 in general shows a more central distribution compared to the adult N170, which may account for the more centrally distributed emotion effect in the current study. There are also studies investigating the adult N170 that did not find effects of emotional expressions on N170 amplitude (see Eimer & Holmes, 2007, for a review). It may be that the infant N290 is more sensitive to emotional expressions in the face than the adult component. There is evidence that the N290 component, compared to the adult N170, is less fine-tuned to the structural encoding of faces (Johnson et al., 2005), which might be relatively independent from emotional expression processing in adults (Eimer & Holmes, 2007). For instance, the infant N290 is sensitive to gaze direction in static pictures, whereas the N170 in adults is not (Farroni et al., 2002). This lack of specificity of infants' neural responses has been seen as evidence for an interactive specialization of the infant brain toward the highly specialized adult social brain network during the first years of life (Johnson, 2000).

The P400 on central occipital channels was substantially more positive as a response to angry compared to fearful faces. As indicated by the additional peak-to-trough analysis, the latter finding is not driven by carryover effects due to the earlier occurring negative N290. Leppänen et al. (2007) found effects of emotional expression on P400 amplitude on more lateral semimedial posterior channels. However, in the study by Leppänen et al., a different configuration of channel sites was used which makes it difficult to directly compare between results from both studies. Further, Leppänen et al. did not test infants' reactions to angry versus fearful faces but compared happy, surprised, and angry faces. Most importantly, however, Leppänen et al. rereferenced their data to the average reference, which was not possible for us due to a smaller number of recording channels. The disadvantage of the linked mastoid reference as used in the current study is that ERPs on channel sites near the mastoids, namely P7 and P8, are attenuated, which makes it difficult to detect effects on these channels (Dien, 1998).

Both the N290 and the P400 are being discussed as potential precursors to the adult N170 as they share functional properties with the adult component and become more finely tuned to the processing of human faces during development in the 1st year (see de Haan et al., 2003, for a review). It has been proposed that the N290 and P400 reflect neural processes that later in development become integrated in a single component, the N170 (de Haan et al., 2003). Our findings suggest that in terms of emotional facial expression processing, the N290 may be more similar to the adult N170 than the P400. But it has to be kept in mind that such conclusions can only be drawn under the assumption that similar processes affect infant and adult face processing, which is rather unlikely. Presumably, familiarity with facial expressions is another factor that might affect even early neural responses. This assumption, however, remains to be tested.

In contrast to a previous study by Farroni et al. (2002), no main effect of eye gaze direction was found for either of the two posterior components. However, in the current study, a different age group was tested and emotionally significant instead of neutral stimuli were applied. Furthermore, methodological differences may account for the discrepancy. We rereferenced EEG data to the linked mastoids instead of the average of all applied channels, used a different baseline correction, and, due to our recording system, we were not able to assess the same channels that were investigated by Farroni et al.

The components investigated in the current study may be part of a developing neural threat detection system. A relationship between amygdala activation and the perception of threatening stimuli and fear is a very consistent finding in studies with adults (Adolphs, 2002; LeDoux, 2003). Empirical evidence even suggests a direct subcortical pathway from the thalamus, a relay station for sensory input, to the amygdala, without passing sensory cortices (Morris, Öhman, & Dolan, 1999). This provides a very fast and efficient way to drag attention in a bottom-up kind of fashion to potentially threatening information, before conscious and more elaborate processing of the fear-eliciting stimuli takes place. It may be that attention is drawn quickly and automatically to angry faces with direct eye gaze already in infancy as they are very immediate indicators of threat and elicit activation in subcortical structures, which then modulate activation in cortical structures related to attentional processes (see also Leppänen et al., 2007).

The current findings support evidence from behavioral studies in which infants at the age of 7 months used emotional expressions provided by adults in association with referential cues to disambiguate potentially dangerous situations or ambiguous behavior (Striano & Rochat, 1999; Striano & Vaish, 2005). According to a definition by Feinman et al. (1992), this behavior can be called social referencing. Feinman et al. defined three elements of social referencing in infancy: (a) seeking information in adults in novel or ambiguous situations, (b) associating the referent with the social message, and (c) regulating behavior in response to the provided information. Still, the developmental course or even onset of social referencing is currently unknown because almost all studies in this field investigated infants from the age of 12 months onward. Because infants are constantly encountering situations they might perceive as novel and ambiguous, it makes sense that they try to obtain information from other people in form of social cues, like eye gaze and facial expressions, much earlier.

In sum, the current findings further our knowledge of neural face processing in infancy. Amplitudes of two face-sensitive posterior components were affected by angry and fearful facial expressions. The Nc was also sensitive to our manipulation of eye gaze direction, indicating enhanced attentional arousal when angry faces were shown with eye gaze directed at the infants. We conclude that infants at the age of 7 months are already sensitive to social signals that indicate threat in the environment. This highly adaptive early competency is most likely an important precursor to social referencing behavior.

Fetal Substance Exposure and Cumulative Environmental Risk in an African American Cohort

Chie Yumoto, Sandra W. Jacobson, and Joseph L. Jacobson
Wayne State University

Two models of vulnerability to socioenvironmental risk were examined in 337 African American children (M = 7.8 years) recruited to overrepresent prenatal alcohol or cocaine exposure: The cumulative risk model predicted synergistic effects from exposure to multiple risk factors, and the fetal patterning of disease model predicted that prenatal insult will increase vulnerability to environmental risk. Four or more risks emerged as a threshold for poorer cognitive and behavioral outcome among the non-substance-exposed children, whereas substance-exposed children showed greater vulnerability to lower levels of environmental risk. Cumulative risk was associated with increased delinquent and internalizing behaviors only for the substance-exposed group. Results support the cumulative risk model for non-substance-exposed children and increased vulnerability to environmental risk among the substance-exposed group.

A wide range of factors in the social environment has been shown to put the child at risk for poorer cognitive and emotional development. One approach to understanding the effects of multiple risk exposure on children's outcomes has focused on the examination of cumulative risk. The cumulative risk model hypothesizes that the total number of risk factors to which the child is exposed is critically important in predicting child maladjustment (Garmezy, 1985; Rutter, 1979; Sameroff, Seifer, Baldwin, & Baldwin, 1993). This model suggests that, regardless of the specific risk factor, as the number of risk factors increases, child psychosocial adjustment becomes increasingly compromised. An alternative model for examining the impact of socioenvironmental risk focuses on the moderating impact of fetal patterning of adult disease. This approach is based on evidence from developmental biology and animal studies suggesting that environmental influences operating in utero can affect the propensity for a disease that may not become manifest until later in development (Gluckman & Hanson, 2004; Wadhwa, 2005). It is hypothesized that an intrauterine event may alter neural development so as to render certain individuals at risk for pathology later in life, increasing vulnerability to chronic illness, including depression, anxiety disorders, schizophrenia, and drug abuse (McDonald, Devan, & Hong, 2004). One implication of this model is that an intrauterine insult, such as fetal alcohol or drug exposure, might increase vulnerability to socioenvironmental risk factors encountered by a child who is reared in a less than optimal environment. The study reported here examined the impact of socioenvironmental risk on cognitive and behavioral outcomes from the perspectives of both models—cumulative risk and fetal patterning of disease—using data from a prospective longitudinal study of inner-city African American children.

Cumulative Risk

A cumulative risk model provides information regarding the number of risk factors the child can "tolerate" before his or her psychosocial adjustment deteriorates markedly (Jones, Forehand, Brody, & Armistead, 2002). For example, in the Isle of Wight study, when using a risk score based on the presence or absence of up to six risk factors (e.g., low socioeconomic status [SES], overcrowding, maternal

psychiatric disorder), the incidence of child psychiatric diagnosis increased sevenfold when the total risk score was 4 or more (Rutter, 1979). Werner and Smith (1982) used a set of 12 risk variables, including poverty, parental psychopathology, and disruption of family unit, and found that children with risk scores of 4 or more at 2 years of age had significantly poorer quality of adaptation at ages 10 and 18 than children with fewer than 4 factors. Applying this model to cognitive outcomes, Sameroff et al. (1993) used a cumulative risk index in their longitudinal study of IQ scores in 4- and 13-year-old children whose mothers were recruited to overrepresent maternal mental illness. The authors examined 10 risk factors (minority group status, occupation of head of household, maternal education, family size, father absence, stressful life events, parenting perspectives, maternal anxiety and mental health, and mother – child interaction—each of which was dichotomized as high or low risk), and a risk index score was calculated based on the number of risk factors in the child's family. They found that IQ scores decreased at both ages as the number of risks increased, with the risk index accounting for 34% of the variance in IQ at 4 years and 37% at 13 years. This effect persisted even after SES was controlled statistically and was still substantial after adjustment for the effects of maternal IQ.

Burchinal, Roberts, Hooper, and Zeisel (2000) compared the predictive power of the cumulative risk approach, in which each risk factor is dichotomized to permit tabulation of the number of high risks to which the child is exposed, with a multiple regression approach, in which child outcomes are predicted from individual risk variables examined simultaneously. The authors note that the multiple regression approach retains the full predictive power of the original continuous risk measures and permits evaluation of the relative importance of each predictor. An important advantage of the cumulative risk approach is that it permits examination of the hypothesis that the impact of multiple risks becomes exacerbated after the number of risks to which the child is exposed exceeds a given threshold.

African Americans have been underrepresented in studies examining cumulative risk, and some studies that have examined cumulative risk in African American children have yielded different findings from those studying Caucasian children. Deater-Deckard, Dodge, Bates, and Pettit (1998) found that individual differences in the increase in externalizing behaviors between 5 and 10 years of age were related to both individual risk factors and cumulative risk. However, their results suggested that most of the prediction of externalizing behavior from cumulative risk was found among Caucasian rather than African American children. Similarly, Gerard and Buehler (2004) found that the association of their cumulative risk measure with conduct problems in 7th- to 11th-grade children was stronger for Caucasian than for African American youth. In the Sameroff et al. (1993) study, the effect of the cumulative risk at age 4 years was also found only among the Caucasian families, although it was evident within both the Caucasian and the African American families at 13 years.

An improved understanding of vulnerability to socioenvironmental risk in the African American population is particularly important given that this population is disproportionately exposed to environments with high levels of psychosocial risk (McLoyd, 1990). In a study of 277 African American children living in single-mother households, Jones et al. (2002) found that cumulative risk was not related to externalizing problems but was predictive of internalizing problems. Among the individual risk factors that these authors examined, only inadequate parenting was significantly related to externalizing problems, whereas maternal depressive mood and inadequate parenting were related to internalizing problems. Kim and Brody (2005) examined risk factors longitudinally using the same data set. They found that an accumulation of family risk factors at 11 years of age was linked with maternal psychological functioning at 12 years of age, which forecast competence-promoting parenting practices at 13 years of age. These parenting practices indirectly predicted externalizing and internalizing behaviors 2 years later, a process that was mediated by youth self-regulation at 14 years of age. Thus, cumulative risk impacted the child's later behavior by influencing the child's psychosocial experiences, including interaction with his or her parents.

Fetal Origins of Vulnerability to Socioenvironmental Risk

Numerous studies have examined the relation of prenatal exposure to alcohol and illicit drugs to cognitive and emotional development. Fetal alcohol spectrum disorder (FASD) ranges from the most severe form—fetal alcohol syndrome (FAS), which is characterized by a distinctive craniofacial dysmorphology, small head circumference, and pre- and/or postnatal growth retardation (Hoyme et al., 2005)—to alcohol-related neurodevelopmental disorder (ARND), a term applied to children exposed prenatally to alcohol who lack the characteristic FAS dysmorphology but exhibit measurable, albeit generally subtler, neurobehavioral deficits (Hoyme et al., 2005; Stratton, Howe, & Battaglia, 1996). Although many children with FAS are mentally retarded (IQ < 70), most children with ARND perform in the normal range (Goldschmidt, Richardson, Stoffer, Geva, & Day, 1996; Mattson, Riley, Gramling, Delis, & Jones, 1997; Streissguth, Barr, & Sampson, 1990; Streissguth et al., 1991). These effects are generally more severe in children whose mothers were older at time of delivery and/or had a history of alcohol abuse problems and less severe in those who received more optimal parental intellectual stimulation and emotional support (S. W. Jacobson, Jacobson, Sokol, Chiodo, & Corobana, 2004). In addition to its effects on cognitive development, prenatal alcohol exposure has been linked to depression in children (O'Connor et al., 2002) and adults (Carmichael, Feldman, Streissguth, Sampson, & Bookstein, 1998; Famy, Streissguth, & Unis, 1998; Spohr & Willms, 1993; Steinhausen, Willms, & Spohr, 1993).

Because the biological insult associated with prenatal substance exposure is likely to be confounded with environmental influences associated with maternal drinking during childhood, it is important to try to distinguish these influences. O'Connor and Paley (2006) found that whereas prenatal alcohol exposure was associated with increased depressive symptoms in the child, these symptoms were not related to current maternal drinking patterns or depression, supporting the hypothesis that fetal exposure plays a critical role in increasing vulnerability to child depression. Similarly, S. W. Jacobson et al. (2006) found that prenatal alcohol exposure was predictive of teacher reports of externalizing problems in the classroom but that these problems were unrelated to current maternal drinking, again suggesting a particular role for fetal exposure in increasing the risk of developing emotional problems in childhood.

Prenatal exposure to cocaine has also been studied in relation to childhood cognitive and emotional development. Coles and Black (2006) point out that, by contrast to fetal alcohol exposure, findings on the effects of prenatal cocaine exposure have been mixed, with the clearest effects seen in cases of heavy cocaine exposure (Alessandri & Bendersky, 1998; Frank & McCarten, 1999; S. W. Jacobson, Jacobson, Sokol, Martier, & Chiodo, 1996; Singer et al., 2001; Singer et al., 2002). There have been relatively few reports of adverse effects on cognitive performance, play behavior, academic achievement, and classroom behavior (Frank et al. 2002; Mayes, 2002; Mayes, Molfese, Key, & Hunter, 2005). The effects have been found primarily on behavioral problems, task persistence and attention, and language performance. Bendersky, Bennett, and Lewis (2006) examined childhood aggression at 5 years of age in a multiple risk model that included cocaine exposure, environmental risk, and gender as predictors and found that all three of these factors were related to a composite aggression score based on reports from multiple informants. Carta et al. (2001) examined the effects of cumulative prenatal substance exposure and cumulative environmental risk on the developmental trajectories of 278 infants, toddlers, and preschool children. Both prenatal exposure and environmental risk added unique variance to the prediction of rate of growth and developmental level and after controlling for birth weight and gender.

The studies to date have focused primarily on detecting main effects of prenatal substance exposure on long-term outcome after controlling for the influences of the social environment. However, studies on preterm infants have demonstrated that fetal and neonatal insult can also increase vulnerability to environmental risk. For example, Levy-Shiff, Einat, Mogilner, Lerman, and Krikler (1994) examined the role of biological and psychosocial factors in predicting long-term outcome in adolescents who were born prematurely at very low birth weight compared with those who were born full term at normal birth weight. They found that SES predicted visual–motor coordination and hyperactive behavior in the very low-birth-weight group but not in the normal-birth-weight group, indicating an interaction between biological vulnerability and environmental risk. Landry, Smith, Swank, Assel, and Vellet (2001) studied the role of early versus ongoing maternal responsiveness in predicting cognitive development in full-term and preterm children at five ages ranging from 6 months to 4 years. They found that both preterm and full-term children's developmental rates in cognitive skills were close to the expected gains of 12 months per year with consistently high levels of responsive parenting. In contrast, preterm children's gains were only 9 months per year, compared to 11 months per year gained by full-term children, when parented by consistently low-responsive mothers. Thus, their data demonstrate the greater vulnerability of children who have experienced an early biological insult to less than optimal parental responsiveness (see also Parker, Greer, & Zuckerman, 1988). Whereas most of these studies have focused on specific environmental risks, the few that have examined the impact of neonatal insult on increased vulnerability to cumulative risk lacked an appropriate control group (e.g., Escalona, 1982). Based on these studies from the preterm literature, we hypothesize that children who are biologically vulnerable as a result of prenatal alcohol or drug exposure and are also exposed to cumulative environmental risks may also be at "double jeopardy" for poor outcomes (Carta et al., 2001).

Aims of the Study

The principal aim of this study was to examine the degree to which cumulative risk and fetal substance exposure modify vulnerability to socioenvironmental risk in a sample of economically disadvantaged, African American inner-city children. We looked at socioenvironmental risks associated with poor outcome and compared their cumulative effects on the child's cognitive and emotional development in prenatally exposed and nonexposed groups. The goal was to examine whether cumulative risk operates differently in these two groups, as well as the degree to which the impact of cumulative risk in the nonexposed African American children resembles that reported in studies of Caucasian children. In addition, it was hypothesized that children who were prenatally exposed would be more vulnerable to cumulative risk factors. Specifically, we predicted that the magnitude of association between risk factors and negative outcome would be stronger in exposed children and that the threshold for a poorer outcome would be lower among children who were exposed to substances prenatally than those who were not.

Method

Participants

Mothers were recruited during pregnancy for a longitudinal study on the effects of prenatal exposure to alcohol and cocaine on child development (S. W. Jacobson et al., 2004; S. W. Jacobson et al., 2006). All African American women were screened for alcohol consumption during their first visit to a prenatal clinic in a large urban maternity hospital ($M = 23.4$ weeks of gestation, $SD = 7.9$) from 1986 to 1989 using a timeline follow-back interview (S. W. Jacobson, Chiodo, Jacobson, & Sokol, 2002). Those averaging seven drinks per week or more at the time of conception (≥ 0.5 oz absolute alcohol [AA] per day), the lowest level at which adverse effects have been observed (J. L. Jacobson & Jacobson, 1994; J. L. Jacobson, Jacobson, Sokol, & Ager, 1998), were invited to participate in the study in order to overrepresent women who were drinking at moderate to heavy levels during pregnancy. A random sample of 5% of the abstainers and lighter drinkers (< 0.5 oz AA/day) from the clinic population were also invited to participate. In addition, the sample includes 78 women who reported heavy cocaine (≥ 2 days per week), light alcohol ($<$ seven drinks per week) use at the time of recruitment. The inclusion of this subgroup substantially reduced the confounding of prenatal alcohol and cocaine exposure (S. W. Jacobson et al., 1996); only 8 moderate to heavy drinkers reported heavy use of cocaine at recruitment. Mean maternal age at recruitment was 26.4 years ($SD = 6.0$), with 6.3% between 14 and 18 years. Infant exclusionary criteria included birth weight $< 1{,}500$ g, gestational age < 32 weeks, major chromosomal anomalies or neural tube defects, or multiple births. A total of 480 children and their mothers were recruited and assessed in the laboratory during infancy.

The sample evaluated in this study comprised the 337 children and their mothers or current primary caregivers who were assessed at 7.5 years of age ($M = 7.8$, $SD = 0.3$). A comparison of the 7.5-year study participants (70.0%) with those lost to follow-up (30.0%) indicated no differences in SES, maternal educational level, alcohol consumption at conception, drug use during pregnancy, or psychopathology (all $ps > .20$). Retention rates were similar in the exposed (72.1%) and nonexposed (66.3%) groups, $\chi^2(1) = 1.60$, *ns*. The only significant difference was that the mothers who participated in the follow-up were slightly older ($M = 26.7$) compared with 25.5 years for nonparticipants, $t(478) = -2.07$, $p < .05$.

To examine the degree to which the impact of socioenvironmental risk may differ depending on prenatal exposure history, two groups were created based on prenatal alcohol and cocaine exposure. The "exposed" group consisted of 227 children whose mothers reported consuming ≥ 0.5 oz AA/day (the equivalent of one or more standard drinks/day) at time of conception or using cocaine at least once per week during pregnancy. The "nonexposed" group consisted of 110 children whose mothers drank < 0.5 oz AA/day with no or, at most, rare, minimal cocaine use during pregnancy. Most of the prenatal alcohol exposure in the exposed group was in the moderate range ($M = 1.3$ oz AA/day, $SD = 2.3$), and only 3 children met criteria for a diagnosis of FAS. When averaged across pregnancy, cocaine was used regularly (≥ 1 day/week) by 7.4% of the mothers.

At the 7.5-year visit, the biological mother was the primary caregiver for a large majority of the children (see Table 1). The primary caregivers for the remaining children were the father (1.3%) or a family relative, usually a grandmother (8.5%) or aunt (1.3%); 1 child (0.3%) had been adopted by foster parents. Median SES for both the exposed and nonexposed groups fell in the fourth level on the Hollingshead (1975) scale, the second lowest of five levels on the scale.

Table 1
Sample Characteristics

	Nonexposed (n = 110)		Exposed (n = 227)		
	M or %	*SD*	*M* or %	*SD*	*t* or χ^2
Maternal/primary caregiver

$*p < .05$. $**p < .01$.

Differences between the nonexposed and exposed groups were observed on four demographic measures. The mothers of the exposed children were older, higher in parity, and less likely to be married, and the exposed children were more likely to be male. Because the difference in parity was a consequence of the difference in primary caregiver age, parity was not considered further. Caregiver age and marital status and child gender were included in the regression analyses described in the following, where appropriate, to control for their potential confounding effects.

Procedures

All child assessments were conducted by examiners who were blind with respect to the child's prenatal exposure and risk status. Procedures were approved by the Wayne State University Human Investigation Committee. Written informed consent was obtained from the mother/primary caregiver at recruitment and at the 7.5-year assessment, and oral assent from the child at 7.5 years. Child cognitive performance was assessed in the laboratory, and behavior problems were rated by the child's classroom teacher. The primary caregiver was interviewed in detail about her current alcohol and drug consumption and other socioenvironmental factors and was administered a test of verbal competence and a test assessing severity of alcohol-related problems. The primary caregiver received monetary compensation and a photo of the child, and the children received a small gift for their participation.

Assessment Battery

Eight risk variables in the child's social and family environment were included in the analyses reported here. Six of these constructs were adapted from Sameroff et al.'s (1993) study, which is a landmark study in examining the effects of cumulative risk on child development. Given the focus of this study on prenatal substance abuse exposure, current substance abuse and parental violence, which often accompanies substance abuse, were also included in the analyses. In order to calculate the cumulative risk index, each of these variables was dichotomized using the criteria listed in the following. Missing data were estimated by using the group median of the exposure group to which the participant belonged. Table 2 summarizes the risk cutoff criteria and presents the percentage of each group that was categorized as high risk.

SES. Numerous studies have demonstrated that lower SES is associated with a wide range of poorer outcomes in children, including cognitive and socioemotional functioning (e.g., Bradley & Corwyn, 2002) and neurocognitive abilities (e.g., Noble, McCandliss, & Farah, 2007). In this study, SES was computed on the Hollingshead (1975) scale separately for the

Table 2

Risk Factors and Cutoff Scores

			% in risk group			Coefficient of variation	
	Measure	Risk cutoff	Nonexposed	Exposed	χ^2	Nonexposed	Exposed
Socioeconomic status	Hollingshead scale[a]	< 20	25.5	39.2	6.18*	0.36	0.46
Number of children	—	≥ 4	13.6	11.9	0.21	0.93	0.89
Presence of father	Lives with biological father	Father absent	82.7	80.2	0.31		
Stressful life events	Life Events Scale[b]	Highest quartile	22.7	28.2	1.14	0.78	0.77
Depression	Beck Depression Inventory[c]	≥ 16	11.8	18.5	2.42	1.00	0.83

*$p < .05$. **$p < .01$.

primary caregiver and partner based on their educational attainment and occupational status, which was averaged together if both were employed; if not, SES was based on the educational attainment and occupational status of the head of household. The continuous Hollingshead SES measure ranges from 8 to 66, which is then grouped into five SES levels; when SES was dichotomized for risk categorization, a score < 20—the lowest of the five Hollingshead SES levels—was classified as high risk.

Number of children at home. It has been shown that having a larger number of children in the home is associated with poorer child cognitive outcome (Luster & McAdoo, 1994). In our study, data on number of children younger than 18 years living in the household were obtained. Following Sameroff et al. (1993), four or more children was considered as high risk.

Presence of father at home. The primary caregiver was asked whether the child lives with his or her father. Although we obtained information regarding the presence of biological fathers, stepfathers, and any father figures (e.g., grandfathers, uncles), the absence of the biological father was used as the high-risk category criterion in this study based on our finding that only the presence of the biological father protected against psychosocial risk in this population (Yumoto et al., 2002). In this sample, it was common for children to have second households where they spend weekends or holidays. However, the biological father was considered to be "present" only when the child lived with him in the primary household.

Stressful life events. Negative life events experienced by primary caregivers (e.g., job loss, divorce, or illness) have been found to be related to children's depression (Compas, Howell, Phares, Williams, & Giunta, 1989), delinquency (Tolan, 1988), aggression (Attar, Guerra, & Tolan, 1994), and cognitive performance (Krishnakumar & Black, 2002). Information was obtained using an adaptive version of the Schedule of Recent Events (Holmes & Rahe, 1967), on which primary caregivers rated any of 43 events they experienced during the preceding year in terms of how stressful they found each event. The continuous measure of life stress consisted of the sum of these ratings; a score in the highest quartile was used as the risk cutoff. One case was missing data on the Schedule of Recent Events and was estimated by using a group median.

Depression. Maternal depression has been shown to be related to children's behavior problems, including aggression, anxiety, and social incompetence (Dodge, 1990) and externalizing problem behaviors (Krishnakumar & Black, 2002). To assess maternal/primary caregiver depression, the present study used the Beck Depression Inventory (BDI; Beck & Steer, 1987), which was also highly correlated with the Global Severity Index on the Symptoms Checklist 90–Revised (Derogatis, 1992) in this sample ($r = .73$, $p < .001$). We used the BDI score of 16 or above, which is considered indicative of moderate to severe depression, as the high-risk cutoff.

Parent–child interaction. Quality of the home environment, as measured by the elementary age version of the Home Observation for Measurement of the Environment (HOME; Caldwell & Bradley, 1984), has been found to be related to child cognitive functioning among 6- to 9-year-old African American children (Luster & McAdoo, 1994). In addition, emotional quality of the parent–child relationship on the elementary age HOME was significantly related to both internalizing and externalizing behaviors in children aged 6–10 years (Wasserman, Miller, Pinner, & Jaramillo, 1996). In our study, scores on two subscales from the HOME—verbal responsivity and emotional climate—were used to assess quality of primary caregiver–child interaction. The parent–child interaction variable was constructed by combining the standardized scores on these two subscales. Both subscales comprised largely examiner ratings based on the observation of the emotional quality of interaction between the primary caregiver and the child. Although mean interobserver reliability was not available for these specific items at this age, previous interobserver reliability on the HOME for this cohort averaged 95% (range = 88%–100%; S. W. Jacobson, Jacobson, Sokol, Martier, & Ager, 1993) and the HOME data obtained at this age were predictive of child IQ (S. W. Jacobson et al., 2004), as reported in other studies. A score in the lowest quartile of the sample distribution, indicating low sensitivity and cold emotional climate at home, was used to define the risk category. For two missing cases, the group median was used to estimate missing values.

Parental violence. Exposure to domestic violence, as measured by the Conflict Tactics Scale (CTS; Straus, 1979), has been linked to increased internalizing and aggressive behavior problems (Holden & Ritchie, 1991) and increased general psychopathology among 6- to 12-year-olds (McCloskey, Figueredo, & Koss, 1995). The CTS assesses the incidence and severity of verbal and physical conflict between the primary caregiver and his or her partner. Scores on the CTS violence scale falling in the top 5% of the national norms for this scale were considered high risk.

Primary caregiver's current substance abuse. Parental substance abuse has been considered a significant risk factor that negatively impacts on children's cognitive functioning and is related to increased externalizing and internalizing behaviors (Moss, Vanyukov, Majumder, Kirisci, & Tarter, 1995; Nunes et al., 1998; Puttler, Zucker, Fitzgerald, & Bingham, 1998; Weinberg, 1997; Wilens et al., 2002). We assessed current substance abuse by the primary caregiver based on the following three measures: (a) frequency of alcohol use, (b) frequency of opiate and cocaine use, and (c) Michigan Alcoholism Screening Test (MAST; Selzer, 1971) score. The MAST is a 25-item self-report measure widely used to identify problems related to alcohol consumption, such as alcohol-related loss of job or friendship or arrest for driving while intoxicated. A positive MAST score (≥ 5) indicates that the respondent has experienced psychosocial and/or physiological problems related to alcohol abuse and is alcoholic or at risk for alcoholism. The continuous variable used to measure current substance abuse was created by averaging standardized scores for ounces of AA per day, days per month of opiate and cocaine use, and the MAST score obtained at the 7.5-year follow-up assessment. For six cases that were missing one or two of the aforementioned variables, the median of the standardized scores for each exposure group was used to estimate missing values. The high-risk group for current substance abuse comprised primary caregivers who currently drank at least 2 oz AA (four or more standard drinks)/day, currently used cocaine once/week or more, or scored 5 or more on the MAST.

Table 2 presents the coefficients of variation (CV; *SD/M*) for the eight risk factors in the nonexposed and exposed groups to assess potential restriction of range. Of the five nonstandardized continuous socioenvironmental risk variables, CV for the exposed group was slightly larger on SES (0.5, compared with 0.4), slightly smaller on maternal depression (0.8, compared with 1.0) and parental violence (1.6, compared with 1.9), and very similar on the remaining measures. With regard to the outcome measures, CV for the exposed group was very similar for the three IQ measures, slightly lower for externalizing behavior (1.1, compared with 1.2) and slightly higher for internalizing behavior (1.1, compared with 1.0).

In addition to the eight socioenvironmental risk factors, verbal competence of the child's biological mother was assessed on the Peabody Picture Vocabulary Test–Revised (PPVT–R; Dunn & Dunn, 1981), which is strongly correlated with Wechsler Adult Intelligence Scale full-scale IQ ($r = .72$) and has been validated for use with this cohort (S. W. Jacobson, Jacobson, & Frye, 1991). PPVT–R score was used as a covariate to test the degree to which the socioenvironmental risk factors affect cognitive development over and above the contribution of maternal verbal intellectual competence.

Outcome Variables

The Wechsler Intelligence Scale for Children–Third Edition (WISC–III; Wechsler, 1991) was used to assess the child's cognitive functioning. The WISC–III yields full-scale IQ (FSIQ), verbal IQ (VIQ), and performance IQ (PIQ) scores. The child's classroom teacher was sent the Teacher Report Form (TRF; Achenbach, 1991) to complete and received a small gift when the questionnaire was returned. Four summary measures derived from the TRF were used in the analyses: aggressive behavior problems; delinquent behavior problems; externalizing total score, which comprises the aggressive and delinquent behavior problem scales; and internalizing total score, which consists of the withdrawn, somatic complaints, and anxious depressed scales.

Data Analyses

Dichotomous risk variables were constructed from the social and family variables using the aforementioned criteria. A cumulative risk index was then computed by assigning a score of 1 for the presence of each risk factor. Cumulative risk was defined as the total number of risk factors of the eight examined in this study.

All analyses were conducted separately for the substance-exposed and nonexposed groups. Multiple regression analyses were conducted using the eight risk variables as continuous measures to examine the associations of social and family variables with the child outcome variables. Hierarchical regression analyses were then conducted to control for three additional sociodemographic potential confounding variables—primary caregiver's age and marital status and child gender—by including all the risk variables in the first step and the additional potential confounders in the second step.

Following these analyses, a correlational analysis was conducted to examine the relation of cumulative risk to the outcome variables. VIQ and PIQ scores were then examined in relation to the cumulative risk score in analyses of covariance (ANCOVAs) to detect whether there were thresholds above which performance is affected particularly strongly, after controlling for the biological mother's verbal competence. The cumulative risk index was recoded into four groups (0–1, 2, 3, and 4 or more) to ensure a sufficient number of cases in each group. Analyses of variance were conducted to assess whether there were threshold effects in the relation of cumulative risk to the behavior problem outcomes assessed. Post hoc comparisons were based on least square difference (LSD) analyses.

Results

Table 3 presents correlations among eight risk factors for each group. The highest correlation among the risk factors in both the nonexposed and the exposed

Table 3
Correlations Among Risk Factors

	Socioeconomic status (SES)	Number of children	Presence of father	Stressful life events	Depression	Parent–child interaction	Parental violence	Current substance use
SES	—	−.23*	.12	.14	−.02	.10	.02	.02
Number of children	−.05	—	.18†	.10	.05	−.18†	−.05	−.02
Presence of father	.17*	.06	—	.09	−.08	.10	−.02	.01
Stressful life events	.02	.14*	.09	—	.48***	−.08	.30**	.21*
Depression	−.09	.06	.06	.54***	—	−.06	.29**	.11

groups was between the primary caregiver's depression and stressful life events in the past year. In the nonexposed group, the next highest correlations were between stressful life events and parental violence and between current substance abuse problems and parental violence. In the exposed group, the next highest correlation was between current substance abuse problems and stressful life events. In the exposed group, SES, primary caregiver's depression, and primary caregiver's current substance abuse problem were all significantly correlated with the responsiveness and emotional climate at home, whereas none of these risk factors were associated with quality of home environment in the nonexposed group. Another difference observed between two groups was in the relation between the primary caregiver's depression and substance abuse, which was significant only in the exposed group.

When the risk factors were examined as continuous measures, the nonexposed and exposed groups differed on only three. Mothers of the substance-exposed children were more likely to have current substance abuse problems, $t(335) = -7.72$, $p < .001$; be depressed, $t(335) = -2.68$, $p < .01$; and report more stressful life events in the previous year, $t(335) = -2.14$, $p < .05$. Although we have previously reported effects of prenatal alcohol exposure on IQ (S. W. Jacobson et al., 2004) and TRF behavior problems (S. W. Jacobson et al., 2006), in these analyses, no differences in mean IQ, delinquency, aggression, or internalizing or externalizing behavior problem scores were found between the nonexposed and exposed groups because effects of prenatal alcohol and cocaine exposure were combined in this study of environmental risk, thereby presumably masking their specific teratological impact (see Table 4).

Table 4
Mean IQ and TRF Scores (SDs) by Exposure Group

	Nonexposed	Exposed	*t* value
WISC-III[a]			
Full-scale IQ	85.6 (13.1)	83.6 (11.9)	1.4
Verbal IQ	89.0 (12.9)	86.6 (12.1)	1.6
Performance IQ	84.5 (13.6)	83.2 (12.7)	0.9
TRF[b]			
Delinquency	1.9 (2.4)	2.4 (2.8)	−1.6
Aggression	8.0 (10.2)	10.3 (11.8)	−1.5
Externalizing	9.9 (12.0)	12.7 (14.1)	−1.6
Internalizing	7.1 (6.8)	6.1 (6.4)	1.3

Note. WISC−III = Wechsler Intelligence Scale for Children−Third Edition; TRF = Teacher Report Form.
[a]*ns* = 110 for nonexposed and 227 for exposed groups. [b]*ns* = 80 for nonexposed and 171 for exposed groups.

Multiple Regression Analyses

Table 5 summarizes the results from the multiple regression analyses. The simple correlations relating the cumulative risk index score with the outcome variables are shown in the bottom row. The principal predictors of FSIQ for the nonexposed group were number of children living at home and parental violence, with an effect of SES falling short of significance. For the children in the exposed group, SES and parental current substance abuse were the principal predictors of FSIQ. Similar patterns were observed with VIQ and PIQ, except that having a biological father living at home was negatively related to PIQ in the exposed group, $\beta = -.14$, $p = .04$, and, for the nonexposed group, parental violence was related to VIQ, $\beta = -.25$, $p = .01$, but not to PIQ. The multiple *R* based on the eight discrete risk factors measured as continuous variables was markedly stronger than the *r* for cumulative risk index for both groups. Moreover, in each regression, the multiple *R* was markedly stronger than the individual standardized regression coefficients, indicating that the combined effect of those risk factors measured as continuous variables exceeds that associated with any of the individual risk factors.

Differential patterns of risk for the TRF scores were also observed for the nonexposed and exposed groups, with one notable exception. The primary caregiver's responsivity and emotional climate at home predicted externalizing behavior problems (i.e., delinquent and aggressive behaviors, and the externalizing total score) for both groups. Whereas the primary caregiver's depression was related to the externalizing behaviors in the nonexposed group, the primary caregiver's substance use problems were related to delinquent behavior problems only for the children in the exposed group. Internalizing behavior problems were not related to any of the individual risk factors, and the multiple *R* for the regression relating the eight risk factors to internalizing total score was not significant for either group.

The regression analyses shown in Table 5 were repeated to control for primary caregiver's age, marital status, and the gender of the child, to examine whether those demographic variables alter the effects observed in the regression. The results were essentially unchanged, except that the effects of the primary caregiver's responsivity and emotional climate at home on delinquent and aggressive behaviors were reduced somewhat in the nonexposed group when the gender of the child was included in the analyses (externalizing total score was reduced from $\beta = -.26$ to $-.18$; delinquent behavior score, from $\beta = -.24$ to

−.20; aggressive behavior score, from β = −.24 to −.17), suggesting that the effect of quality of parenting on externalizing was possibly due, in part, to the fact that girls, who are less prone to exhibit externalizing behavior, were provided with more optimal interaction and warmer emotional climate at home in the nonexposed group.

Cumulative Risk Index

The cumulative risk index was calculated by counting number of risk factors the child experienced of the eight risk factors examined. Children in the exposed group experienced somewhat more risk factors (M = 3.0, range = 0–7) than those in the nonexposed group (M = 2.4, range = 0–6; t = 14.6, $p < .05$). The correlations of the cumulative risk index with FSIQ and the behavioral outcomes are shown in the bottom row of Table 5. As expected, a higher cumulative risk index was associated with lower FSIQ in both groups. Although the multiple R from the eight-variable regression was significantly related to all child outcome measures except the internalizing total score, the cumulative risk index was not related to the externalizing total score or the aggressive behavior score in either group. The cumulative risk index was related to the delinquent behavior score only in the exposed group. The internalizing total score was also related to the cumulative risk index score only in the exposed group (r = .20, $p < .01$, compared with r = −.02, *ns*, in the nonexposed group).

Threshold Effects

The ANCOVAs revealed different patterns for the exposed and nonexposed groups on VIQ (see Figure 1). The VIQ scores among the children who were not exposed to alcohol or drugs during pregnancy dropped dramatically in the presence of four or more risk socioenvironmental risk factors (LSD p = .05, for three vs. four or more risk factors), whereas the VIQ in the exposed group decreased gradually as the number of risk factors they had experienced increased (r = −.13, p = .06). By contrast, with the PIQ, both groups showed a gradual linear decrease as the number of risk factors increased (see Figure 2; rs = −.15, p = .10, and r = −.14, p = .04, for the nonexposed and exposed groups, respectively).

Differential patterns were also observed for the TRF scores. Figure 3 shows that delinquent behavior observed by the child's teacher significantly increased with four or more risk factors in the nonexposed group (LSD $p < .01$, for three vs. four or more risk

factors). By contrast, delinquent behavior significantly increased after three risk factors in the exposed group (LSD $p < .01$, for two vs. three risk factors). No threshold effects were observed for aggressive behavior assessed by teachers in either group. As shown in Figure 4, the number of internalizing problems reported by teachers increased significantly with four or more risk factors in the nonexposed group (LSD $p = .03$, for three vs. four or more risk factors). In the exposed group, increasing risk was associated with a gradual increase in internalizing total score ($r = .20, p < .01$).

Discussion

A major aim of this study was to examine the impact of prenatal exposure to alcohol and/or cocaine on vulnerability to risks encountered in the childrearing environment. When we previously examined the data looking specifically at moderate to heavy exposure to alcohol during pregnancy on IQ and externalizing behaviors, we reported significant effects of fetal alcohol exposure on IQ, working memory, number processing, and a range of behavioral endpoints on the TRF, using continuous measures of alcohol exposure (Burden, Jacobson, & Jacobson, 2005; Burden, Jacobson, Sokol, & Jacobson, 2005; S. W. Jacobson et al., 2003; S. W. Jacobson et al., 2004; S. W. Jacobson et al., 2006). These and other infant effects were *specific* to prenatal alcohol exposure (S. W. Jacobson, 1998) and different from those found for heavy cocaine or other teratogenic exposures (J. L. Jacobson et al., 1998) for this cohort. The lack of group differences reported here on these outcomes reflects the inclusion of cocaine-exposed children with little or no alcohol exposure in the high-exposure group in this study that was designed to focus on the moderating effects of prenatal substance exposure, thereby obscuring the prenatal alcohol effects. Thus, as expected, the prenatally exposed children as a group did not differ from the nonexposed group on the developmental outcomes examined—IQ and internalizing and externalizing behavior problems. Despite the similar mean IQ and behavior problem scores, however, the data revealed that differences in vulnerability to environmental risk operate in these two groups, thereby supporting the fetal patterning of later development hypothesis. Not surprisingly, current maternal substance abuse impacted more strongly on the IQ scores of the prenatally exposed children, presumably because of its more limited range in the nonexposed group. By contrast, number of children in the household was related to FSIQ only in the nonexposed group. Being raised in a smaller family had a beneficial effect on cognitive performance only for the children not exposed prenatally to alcohol or cocaine.

The findings from previous studies regarding the applicability of cumulative risk models of the impact of socioenvironmental factors on development in African American children have been inconsistent due, in part, to limited sample sizes. Our multiple regression data (Table 5) make clear, however, that the joint effect of multiple environmental risks markedly exceeds that of any of the individual risk factors. In contrast, the cumulative risk index, which is based on dichotomizing each of the risk factors and is, therefore, generally less sensitive (Burchinal et al., 2000), was significant for the cognitive outcomes for both the substance-exposed and the nonexposed children. For the exposed children, the cumulative risk was also related to delinquent and internalizing behaviors. We note that the term *delinquent* is not usually used with early elementary school-aged children and that the children's scores on the TRF delinquency scale were low. The principal TRF delinquent behaviors endorsed by the teachers were breaking school rules and lying or cheating. The data show that the cumulative risk was related to increased incidence of these behaviors at 7.5 years of age among the children exposed to substances prenatally.

It is of interest that the cognitive and behavioral endpoints examined in this study were influenced by different sets of risk factors. Whereas SES, family size, parental substance abuse, and parental violence were the principal risk factors for FSIQ, having an emotionally responsive primary caregiver and a warm emotional climate at home was the most consistent predictor of lower levels of delinquent and aggressive behaviors at school across groups. The presence of the biological father in the home also appears to be associated with reduced delinquent behavior. The inverse relation between maternal depression and externalizing behaviors in the nonexposed group, which was not predicted, suggests that family temperament or modeling parental behaviors may influence whether the child's psychosocial problems will be expressed in the form of delinquent or aggressive behaviors. The identification of the parent–child interaction as the most important socioenvironmental predictor of externalizing behavior problems is consistent with data from another African American sample (Jones et al., 2002). Just as much emphasis has been placed on the importance of intellectual stimulation and emotional support for cognitive development in middle-class Caucasian samples, quality of parenting also appears to be most important for socioemotional development and behavioral outcomes for inner-city African American children.

In the Isle of Wight study, Rutter (1979) found that the relation of the number of risk factors to which the child was exposed to developmental outcome was nonlinear, with a threshold of four or more. Whereas most children are relatively unaffected by three or fewer socioenvironmental risk factors, Rutter's data indicate that exposure to multiple risks interacts so that their effect on development becomes synergistic. It is of particular interest that, similar to Caucasian middle-class cohorts, four or more risks emerged as a threshold in our dose–response analyses of the African American children in our cohort who were not exposed prenatally to alcohol or cocaine for three important outcomes—VIQ, delinquent behaviors, and internalizing behaviors.

The multiple regression and correlational data in Table 5 did not indicate increased vulnerability to socioenvironmental risk in the prenatally exposed group; the multiple *R*s for the regressions and correlation coefficients for the cumulative risk index were generally slightly higher in the nonexposed group. Because the coefficients of variation for the risk factors were similar for the two groups (Table 2), this difference in effect size cannot be attributed to restriction of range in the exposed group. By contrast, the data from the dose – response analyses indicate that the dampening of the effect of exposure to three or fewer risk factors in the nonexposed group was not found in the prenatally exposed group. For most endpoints, each additional risk factor was associated with poorer cognitive performance and increased behavior problems in a linear fashion among the substance-exposed children. Moreover, for the one endpoint where a threshold was observed—delinquent behavior—behavior problems increased at a lower threshold (three or less risk factors) than among the nonexposed children. Another indication of increased vulnerability is the finding that cumulative risk was associated with increased internalizing behavior problems only for the prenatally exposed children. In addition, the data in Table 3 suggest that multiple risk factors are more likely to occur together in the families of the substance-exposed children. Although parental substance abuse, life stress, and maternal depression are moderately intercorrelated in both groups, for the prenatally exposed children quality of parenting, the principal protective factor for externalizing behavior problems, was also more correlated with SES, caregiver depression, and substance abuse, increasing the likelihood of the co-occurrence of multiple risks for the children in that group.

In interpreting the findings, certain limitations of the study should be noted. Because the focus of the study was on economically disadvantaged, inner-city African American families, one must be cautious about generalizing from these findings to other populations, who may have greater access to community or other forms of social support. Because prenatal substance exposure is associated with prematurity and reduced birth weight, the exclusion of very low birth weight and severe preterm deliveries may have reduced the number of more severely affected children in the cohort. In addition, although moderating effects of gender on externalizing behaviors have been reported in children prenatally exposed to alcohol and cocaine (Nordstrom-Bailey et al., 2005), we did not examine the interaction between gender and prenatal substance exposure in this study because the cell sizes in such analyses would have been unduly small. Nordstrom-Bailey et al.'s (2005) data also suggest that prenatal alcohol exposure may moderate prenatal cocaine effects on teacher-reported child externalizing behavior. We did not examine the effects of prenatal alcohol and cocaine exposure separately, however, to optimize cell sample sizes and because our hypothesis regarding fetal patterning focused on the impact of substance exposure generally on vulnerability to socioenvironmental risk.

Despite these limitations, these data lend support to findings of synergistic effects among multiple socioenvironmental risk factors reported in previous studies and provide evidence that four or more risks may be an important threshold for non-substance-exposed, inner-city African American children as well as the Caucasian children examined in previous studies. These data also provide support for the prediction from the fetal patterning of disease model that prenatal exposure to alcohol and/or cocaine can increase vulnerability to socioenvironmental risk. Based on the cumulative risk index and dose – response data, vulnerability to the adverse effects of socioenvironmental risk appears to be enhanced particularly on two endpoints—delinquent and internalizing behaviors.

A conceptual framework based on social ecology, social learning, and social control theories guided identification of social contexts, contextual attributes, and joint effects that contribute to development of adolescent alcohol misuse. Modeling of alcohol use, suggested by social learning theory, and indicators of the social bond, suggested by social control theory, were examined in the family, peer, school, and neighborhood contexts. Interactions between alcohol modeling and social bond indicators were tested within and between contexts. Data were from a longitudinal study of 6,544 students, 1,663 of their parents, and the U.S. Census. All contexts were uniquely implicated in development of alcohol misuse from ages 11 through 17 years, and most alcohol modeling effects were contingent on attributes of social bonds.

A social ecological perspective suggests that multiple social contexts and the interdependencies among contexts must be considered in explaining development of adolescent problem behaviors, such as alcohol misuse. Although adolescent alcohol use and misuse have been recognized as shaped by social contexts and processes (e.g., Brook, Nomura, & Cohen, 1989; Perry, Kelder, & Komro, 1993; Petraitis, Flay, & Miller, 1995), research on higher level contexts, such as schools and neighborhoods, is less common than research on peer and family contexts. Comprehensive examination of the multiple contexts comprising the social ecology of adolescent alcohol use is even more limited. Explanation for the lack of social ecological research may rest in the magnitude of conceptual and analytic demands when multiple social contexts that are themselves multidimensional are jointly considered.

We draw on theories of ecology of human development (Bronfenbrenner, 1977, 1979), social learning (Akers, Krohn, Lanza-Kaduce, & Radosevich, 1979; Bandura, 1977; Petraitis et al., 1995), and social control (Hirschi, 1969; Petraitis et al., 1995) to examine development of alcohol misuse in adolescence by specifying a set of social contexts, attributes of those contexts, and interrelations among those attributes to examine. Our purpose was to use these theories to identify a parsimonious set of contextual attributes, while broadly considering the multiple social contexts in which adolescents' lives are embedded, that in interaction with each other could meaningfully explain development of adolescent alcohol misuse.

Bronfenbrenner's Ecology of Human Development Theory

Bronfenbrenner's theory provides the overarching conceptual framework by establishing a developmental perspective; defining the social contexts for investigation; specifying the need for an inclusive, multidimensional view of these social contexts; and suggesting relationships of the contexts to each other and the

developing adolescent. The central precepts of the ecology of human development are that human development takes place within a set of nested and changing environments and that complex relations within and between those nested environments shape behaviors. Bronfenbrenner suggests an approach to examining interrelations among social contexts by positing that "in ecological research, the principal main effects are likely to be interactions" (Bronfenbrenner, 1977, p. 518).

Bronfenbrenner defines person–environment interrelations in terms of micro-, meso-, exo-, and macrosystems. The first three systems are relevant to the current investigation because they define social contexts. Microsystems are the principal and immediate socialization contexts in which human development takes place: the family, peer, and school contexts for adolescents. An exosystem comprises more remote social environments, such as neighborhoods, in which microsystems are embedded. The concept of mesosystems is that processes operating in different contexts are not independent of each other. According to Bronfenbrenner, a mesosystem is formed from the interrelations among microsystems; as an example, processes in the family may impinge on relationships in the peer group (Bogenschneider, Wu, Raffaelli, & Tsay, 1998).

Theoretical Perspectives Relevant to Specifying Contextual Attributes

Despite the conceptual utility of the ecology of human development, Bronfenbrenner does not provide specificity about the particular attributes of social contexts to measure. Social learning and social control theories are helpful here because both theories situate causes of alcohol use and other problem behaviors in the social environment. Moreover, they are the dominant theoretical perspectives in research on adolescent alcohol and other substance use and have substantial empirical support (Petraitis et al., 1995).

Social learning theory emphasizes exposure to alcohol-using role models and social control theory focuses on the constraining function of social bonds. Social learning theory posits that adolescent alcohol use is a learned behavior acquired through social interactions and reinforcement and the resulting ratio of exposure to prosocial versus antisocial definitions for drinking (Petraitis et al., 1995). The ubiquitous positive association between adolescent drinking and their friends' drinking (e.g., Bauman & Ennett, 1996) is typically understood as evidence of social learning, as is the relationship between parental alcohol use and drinking in their children (e.g., Richter & Richter, 2001).

Social control theory posits that a tendency toward deviance is universally shared but manifested only when the bond between an individual and society is weakened (Hirschi, 1969; Petraitis et al., 1995). The social bond may be weakened when conventional attachments are attenuated as when parent–adolescent closeness is low or parents do not exercise supervision of their adolescents (e.g., Hops, Duncan, Duncan, & Stoolmiller, 1996; Simons-Morton & Chen, 2005), and in the face of stress, such as in high-conflict families (e.g., Aseltine & Gore, 2000; Webb & Baer, 1995). At a higher level, and often understood from the perspective of macrolevel social control theory, adolescent deviance may be due to attenuated bonds in socially disorganized neighborhoods (Elliott et al., 1996; Sampson, Raudenbush, & Earls, 1997).

Conceptual Framework

Figure 1 presents a schematic representation of the conceptual framework guiding the study. Based on the ecology of human development, four social contexts are posited as potentially relevant to development of adolescent alcohol misuse—family, peers, school (microsystems), and neighborhood (exosystem). The arrows between the family, peer, and school contexts indicate interrelations among these microsystem contexts (mesosystems), thus between family and peers, family and school, and peers and school.

Consistent with Bronfenbrenner's injunction to measure the complexity of social contexts, each context is characterized by a set of four variables. The variables are derived from social learning or social control theory, with each variable tailored to the particular context. Modeling of alcohol use by others (family members, friends, schoolmates, neighbors) is measured as the central construct from social learning theory. From social control theory, closeness to others, social regulation, and stress are measured as indicators of social bonds pertinent to constraining deviant behavior. As an example of the tailoring of these social control variables to the context, closeness is operationalized as parent–child closeness in the family context, feelings of closeness among mutual friends in the peer context, overall level of school bonding among all students in the school context, and neighborhood bonding among neighborhood residents.

All four social contexts are expected to uniquely contribute to adolescent alcohol misuse development. In addition, following from Bronfenbrenner's prediction of the primacy of interactive effects, the social learning and social control variables characterizing the contexts are expected to have interactive effects within the four contexts and between the three

Note. Family, peer, school, and neighborhood contexts and their relationships to each other are suggested by the ecology of human development; ovals depict microsystems, arrows depict mesosystems, and the rectangle depicts an exosystem. Characteristics of contexts in bold are derived from social learning theory (modeling of alcohol use) and characteristics in italics are derived from social control theory (closeness, social regulation, stress).

microsystem contexts. Specifically, alcohol modeling effects are expected to vary depending on attributes of the social bonds.

Empirical Support for Interactive Effects Between Social Learning and Social Control Constructs Between and Within Social Contexts

Studies of adolescent alcohol or other substance use in which interactions among social learning and social control constructs were examined are surprisingly limited, whether considering studies that simultaneously considered two or more social contexts or that examined only a single social context. When two or more contexts have been included, family–peer relations have been most commonly studied and mediating effects between social learning and social control constructs examined more often than moderating effects. These studies provide evidence that family attributes such as drug models, parent–adolescent attachment quality, parenting style, and family structure buffer negative peer effects (Brook, Brook, Gordon, Whiteman, & Cohen, 1990; Brook, Whiteman, Gordon, Nomura, & Brook, 1986 A. D. Farrell & White, 1998; Marshal & Chassin, 2000; Mason, Cauce, Gonzales, & Hiraga, 1994).

Several studies have examined interactive effects of social learning and social control constructs on adolescent alcohol use in the family context and, less often, the peer context. Results are mixed in supporting conditional relationships when effects of the parent–child relationship and parent alcohol use were examined. Some studies found evidence for no interactions between parent–adolescent attachment quality and parental alcohol use (Andrews, Hops, & Duncan, 1997; Kandel & Andrews, 1987), whereas others reported amplifying effects of lower levels of attachment quality on parental alcohol use and/or buffering effects of higher levels of attachment quality (Andrews et al., 1997; M. P. Farrell, Barnes, & Banerjee, 1995; Urberg, Goldstein, & Toro, 2005; Zhang, Welte, & Wieczorek, 1997). In the peer context, the relationship between peer and adolescent alcohol use has been shown to be stronger when peer support is high

(Urberg et al., 2005). Similarly, in research on adolescent delinquency, delinquency–peer associations may be stronger among closer friends (Giordano, Cernkovich, & Pugh, 1986; Haynie, 2001).

Study Hypotheses

We test the fundamental premises of the ecology of human development that attributes of multiple social contexts will contribute to development of adolescent alcohol misuse and that interrelations within and between contexts, tested through interactions between social learning and social control constructs, will be important effects. Specifically, we hypothesize that the effects of alcohol use by others will vary depending on closeness, social regulation, and stress, and that the nature of the interactions will vary depending on the context or contexts involved.

Within the family and neighborhood contexts, where adult norms against alcohol misuse are expected, we hypothesize that closeness and social regulation will buffer effects of family and neighbors' alcohol use. Within the peer and school contexts, where the reference is to interactions with other adolescents, closeness and social regulation are hypothesized to amplify effects of friends' and schoolmates' alcohol use. Consistent with these hypotheses, we expect that between-context interactions involving family closeness and social regulation will buffer exposure to alcohol use by friends and schoolmates, whereas peer closeness and social regulation will amplify exposure to alcohol use by schoolmates. Within and between all contexts, we hypothesize that stress will magnify the effect of alcohol use by others. In keeping with the developmental perspective of the ecological framework, we examine the contribution of these contextual effects to growth in adolescent alcohol misuse by modeling trajectories of alcohol misuse from age 11 to age 17 in a general population sample.

Method

Study Overview

The data were from a longitudinal investigation of intrapersonal and contextual factors that influence adolescent alcohol use and other problem behaviors. The study design included four components to enable contextual analyses: (a) a census of adolescents identified by school enrollment and surveyed in school every 6 months for a total of five assessments (Waves 1–5), (b) a simple random sample of parents of the adolescents surveyed annually by telephone for a total of three assessments (Waves 1, 3, and 5), (c) social network analysis of school networks based on friendship nominations collected in the school surveys, and (d) geocoding of all adolescent and parent addresses to allow linkage of the addresses to U.S. Census tracts and block groups. Data collection with adolescents and parents began in spring 2002 and ended in spring 2004.

All protocols were reviewed and approved by the institutional review boards at the University of North Carolina at Chapel Hill and Wake Forest University. The boards approved a waiver of written parental consent. Four weeks prior to data collection, parents were informed about the study through a letter sent both by first-class mail and home with the child. Parents could refuse their child's participation by returning a postage-paid form or by calling a toll-free number. Written adolescent assent was obtained in school at the time of data collection by trained data collectors.

Adolescent Sample and Data Collection

Adolescents enrolled in three public school systems in North Carolina were entered into the study when they were 6th, 7th, and 8th graders and completed the study as 8th, 9th, and 10th graders, respectively. The school systems included a total of eight middle schools, two comprehensive K–8 schools, six high schools, and three alternative schools with middle and high school grades. The high schools were not included until Wave 2 when the first 8th graders transitioned from middle school. Data collection was timed to coincide with the beginning and end of the school year. At each assessment, all enrolled students at the targeted grade levels, except for those in self-contained classrooms for exceptional children and those with limited English language reading skills, were eligible for the study. Thus, students new to the study enrolled at each wave of data collection; approximately 15% of students were newly enrolled at the beginning of each school year and approximately 3% were newly enrolled midyear. Across the five assessments, the samples ranged in size from 5,220 (Wave 1) to 5,017 (Wave 5) adolescents, with 6,891 unique cases across all waves. Response rates at the five waves were 88.4%, 81.3%, 80.9%, 79.1%, and 76.0%, respectively. Approximately one third of students were in each of the three grade cohorts; at Wave 1 the distributions were 35.6%, 33.5%, and 30.9% in Grades 6, 7, and 8, respectively.

Trained data collectors administered questionnaires on at least two occasions at each school to reduce the effect of absenteeism on the response rate. Adolescents completed the questionnaire in approximately 1 hr. Names were not written on questionnaires, and questionnaires were placed in envelopes without names and sealed before returning them to the data collectors. Teachers stayed in classrooms to help maintain order but did not answer questions or walk around the classroom.

Parent Sample and Data Collection

A simple random sample of 1,663 parents of adolescents who completed the Wave 1 survey completed a 25-min telephone interview at Waves 1, 3, and 5. All parents completed the interview in English. Unlike for adolescents, new parents did not enter the study after Wave 1. By design, in the majority of cases (98.2%) the mother or mother surrogate was the parent interviewed. Response rates at the three waves were 79.8%, 82.5%, and 71.8%, respectively. The parent sample was designed to provide sufficient number of cases within each census geographic area to allow aggregate measures of neighborhood context from parent responses to questions about their neighborhood.

Based on self-reports, the mean age of parent respondents at Wave 1 was 40.50 years (*SD* = 7.23). Approximately 59% self-identified as White, 38% as Black, 1% as Hispanic, and 2% as another race/ethnicity. Approximately two thirds (64.9%) reported living in a two-parent household. For 45%, the highest education attained was high school graduate or less.

Social Network Analysis

Social network analysis was conducted on friendships reported by adolescents at each wave of data collection (Ennett et al., 2006). Data collectors provided each student a student directory that alphabetically listed all enrolled students along with a unique four-digit peer identification number for each student. Adolescents identified up to their five closest friends, starting with their best friend. Friends not in the directory were identified by "0000." Because most adolescent friendships are with adolescents in the same school and grade, we bounded social networks by school and grade, with the following exceptions. In high schools and alternative schools, networks were bounded by school only because classes and activities were not grade segregated and therefore cross-grade friendships were likely. In the two K–8 schools, networks also were bounded by school because of their small enrollments. We defined the peer context by the adolescent's set of close friends, including those nominated by the adolescent and those who nominated the adolescent as friend. The school context was defined by the school network to which the adolescent belonged and thus included a larger set of peers than close friends.

Geocoding

The addresses of adolescents and parents at each wave of data collection were sent to a commercial geocoding firm to be matched with U.S. Census tract and block group data in the 2000 decennial census. At Wave 1, 94.6% of the parent sample was matched to a street address and 5.4% was matched to a ZIP centroid; 94.8% of the adolescent sample was matched to a street address, 3.9% to the ZIP centroid, and less than 1% was not matched. The match rates were similar at other waves of data collection. The geocodes represented 158 census block groups and 56 tracts, and they covered all the block groups and tracts in the three-county area as well as some block groups and tracts in contiguous areas where some of the students and parents lived.

We defined the neighborhood context by the U.S. Census block group in which the adolescent lived the first time the adolescent was assessed. Neighborhood assignment was based on block group rather than tract because the smaller size more nearly approximated neighborhoods and comparison of intraclass correlation coefficients for neighborhood measures defined for block groups and census tracts showed greater homogeneity within block groups (data not shown).

Analysis Sample

The analysis sample included all adolescents who participated at any wave of data collection (*N* = 6,891) except for those missing birth date or outside the typical age range of 11–17 years for the grades studied (*n* = 51, 0.7%) or who could not be geocoded (*n* = 296, 4.3%), yielding a sample size of 6,544 (95.0%).

The mean self-reported age of adolescents at Wave 1 was 13.12 years (*SD* = 1.04). About half were male (51%) and the self-reported race/ethnicity distribution was 52% White, 37% Black, 4% Hispanic, and 7% other race/ethnicity. Averaged across all five waves of assessment, approximately 13% of adolescents reported living in other than a two-parent family and for 39% the highest education attained by either parent was reported by the adolescent to be high school or less.

Measures

Measures included adolescent alcohol misuse, social context variables suggested by social learning and social control theories, and demographic control variables. The alcohol and social context variables were collected at all five assessments, allowing construction of time-varying measures. With the exceptions of age and high school enrollment, the demographic variables were constructed as time invariant.

Alcohol misuse. We constructed a scale of alcohol misuse based on eight adolescent self-report items about recent alcohol use. Items measured problematic levels of use (e.g., had five or more drinks in a row, gotten drunk or very high from drinking alcoholic beverages) and negative consequences associated with use (e.g., gotten into a physical fight because of drinking, did something you later regretted because you had been drinking). Each item had five response categories ranging from 0 to 10 or more times in the past 3 months. Because of the skewed distribution of responses, as expected for a general population sample of young people, rather than constructing the scale by summing or averaging responses to the eight items, we used item response theory (IRT) to construct the scale (Thissen, Nelson, Rosa, & McLeod, 2001). Because IRT models require independent cases, we randomly selected one observation per respondent from all the repeated measures. We confirmed that a one-factor model fit the data well, using the weighted least squares estimator implemented in Mplus (Muthén & Muthén, 1998–2006). We used MULTILOG software to run both the graded response model and the nominal model in a comparison to determine which provided a better fit to the data (Thissen, Chen, & Bock, 2003). The nominal model provided a substantially better fit than the graded response model to the observed proportions in the lowest response category (i.e., zero times) for all items. In addition, even though the nominal model was unconstrained, it preserved the ordering of the response categories. Thus, we selected the nominal model. We then used the item parameter estimates to compute scale scores using the maximum a posteriori method (Thissen & Orlando, 2001). The resulting scale more nearly approximated a continuous distribution, with reduced skewness and kurtosis, compared with a summed scale.

Social context. We measured indicators of alcohol modeling, closeness, social regulation, and stress in each social context. Most measures were means of reduced sets of items from existing scales. Specific items were identified for survey inclusion through earlier psychometric analysis of data collected on full scales in a pilot study. Except where otherwise noted, items had either four or five response categories. Cronbach's alphas reported with the measures were averaged across the five waves.

Family context measures, based on adolescent report, were the number of current alcohol users in the family (alcohol modeling), parent–adolescent closeness (closeness), parental supervision (social regulation), and family conflict (stress). The number of drinkers was constructed from items about recent alcohol behavior asked separately for the mother, father, and siblings. Parent–adolescent closeness was measured by two sets of three questions asked separately about the mother and father, such as how close the adolescent felt toward the parent ($\alpha = .80$). Parental supervision was constructed from two sets of three items asked separately for the mother and father from the Authoritative Parenting Scale (Jackson, Henriksen, & Foshee, 1998). The scale measured parental supervisory behavior, such as whether the parent had rules that the adolescent must follow ($\alpha = .84$). Family conflict was measured by three items tapping fighting, throwing things, and sometimes hitting within the family ($\alpha = .85$; Bloom, 1985).

The peer measures were mean alcohol misuse among friends (alcohol modeling), mutual friends' closeness (closeness), relationship closure (social regulation), and adolescent membership in intransitive friendship triads (stress). Friends' alcohol use was based on the set of close friends and was the mean of their self-reported alcohol misuse. Peer closeness measured the mean closeness reported by mutual friends (i.e., friends who reciprocated the adolescent's nominations); thus, it measured how close these friends felt toward the adolescent. Relationship closure, based on adolescent reports, was the mean of three dichotomous items per nominated friend measuring whether the adolescent's parents had met the friend, the adolescent had met the friend's parents, and adolescent and friend's parents had met (Bearman & Moody, 2004). Higher values indicated greater parental knowledge of friends, suggesting both greater intimacy between adolescents and the possibility of more effective parental oversight and regulating influence on the peer context (Coleman, 1988). Peer stress was derived from the social network analysis (Moody, 2000, 2001) that identified intransitive triads to which adolescents belonged, where an intransitive triad was a set of three peers linked through friendship nominations such that a friend's friend was not also a friend of the adolescent. The variable was the proportion of intransitive triads among all the triads to which the adolescent belonged. Whereas transitive triads represented balanced, closed friendship circles, intransitive triads reflected unbalanced and potentially discordant relationships where an adolescent's friendships were not overlapping and thus carried the potential for stress (Bearman & Moody, 2004).

School context measures were based on data from all students in the school network. Measures were mean alcohol misuse in the network (alcohol modeling), school bonding (closeness), relative density of the school network (social regulation), and prevalence of school misbehavior (stress). School bonding was the mean of adolescents' agreement with three items, such as "students at this school are willing to go out of their way to help someone," from a scale measuring caring school communities (α = .84) (Battistich & Hom, 1997). School network relative density, identified through the social network analysis, was the proportion of possible friendship ties present in the school network; the measure adjusted for the fixed number of friend nominations (Moody, 2000, 2001). Higher values indicated greater presence of friendships linking together adolescents in the school and thus more closely knit school communities with presumed greater potential for regulating behavioral norms. School misbehavior was measured with five items from the Problem Behavior Frequency Scale (A. D. Farrell, King, White, & Valois, 2000) that tapped frequency of school-related problem behaviors, such as skipping school and threatening a teacher. Responses were averaged across all students in the school network. Schools with high levels of student misbehavior were assumed to be a stressful environment for adolescents.

We measured neighborhood context attributes, with neighborhoods defined by census block group, based on data from parents residing in each block group, adolescent residents, and the U.S. Census. Because parents were interviewed at Waves 1, 3, and 5 only and because we operationalized time-varying measures for all social context variables, we used the same parent-based neighborhood measures at Wave 2 as at Wave 1, and at Wave 4 as at Wave 3. The measures were the mean alcohol misuse of all adolescents living in the neighborhood (alcohol modeling), mean neighborhood bonding (closeness), mean informal neighborhood social control (social regulation), and mean neighborhood disadvantage (stress). All measures were grand mean centered.

Neighborhood bonding was based on parents' agreement with three items that measured bonding and trust among neighbors (α = .90; Parker et al., 2001). Neighborhood informal social control was constructed from six items that assessed willingness of neighbors to step in and do something when teens were misbehaving, such as damaging property or hanging out and smoking marijuana (α = .91; Sampson et al., 1997). Neighborhood disadvantage was based on parent agreements' with six items regarding physical and social disorder in the neighborhood, such as there being a lot of crime in the neighborhood (Ross & Jong, 2000), and five U.S. Census measures of socioeconomic disadvantage for the block group, such as percentage below the poverty line and percentage of households without a high school degree (α = .84).

Demographics. All measures were based on adolescent self-reports except for high school enrollment, which was derived from school records. Age was measured continuously based on date of birth. Sex was coded so the reference group was female. Race/ethnicity was based on the adolescent's modal response across all waves of assessment and dummy coded to include White (reference group), Black, Hispanic, and other race/ethnicity. Family structure was coded as two parents in the home (reference group) versus some other composition. Parent education measured the highest education attained by either parent and coded as high school graduate or less versus more than high school graduate (reference group). Because family structure and parent education could change over the course of the study, the two variables were coded as the average across the five waves.

Multiple Imputation

As already noted, students could enter the study at any of the five assessments and some students attrited at one or more waves. Of the 6,544 students in the analysis sample, 44.2% participated in all five waves, 18.3% participated in four waves, 15.2% in three waves, 10.9% in two waves, and 11.5% at only one wave. Adolescents missing at one or more waves compared with those continuously assessed once they entered the study were significantly more likely to be male, Black or of other race/ethnicity, live in other than a two-parent household, have parents with lower education, and have higher levels of alcohol use. Of the 1,663 parents, 66.8% completed all three interviews, 20.4% completed two interviews, and 12.8% completed only the first interview. Parents who completed one or two interviews compared with those who completed all three interviews were more likely to be Black, live in other than a two-parent household, and have lower education.

So that complete data sequences were available for all cases (Allison, 2002), we used PAN, a multilevel multiple imputation program appropriate for longitudinal data, to impute five sets of missing values (Schaefer, 2001). Variables included in the missingness equation were the demographics, alcohol misuse, and all social contextual variables at all five waves. We bounded the imputed values to the valid ranges of the data, and allowed all imputed dichotomous variables to range between 0 and 1 rather than rounding values (Allison, 2005).

Statistical Analysis

Because of the nestedness of our data and social contexts, such that repeated measures of alcohol misuse were nested within adolescents and adolescents were nested within neighborhoods and schools, we used a multilevel modeling approach (e.g., Raudenbush & Bryk, 2002). Specifically, we estimated three-level hierarchical growth models with time specified at Level 1, adolescents at Level 2, and neighborhood at Level 3. Four-level models cross-classified by neighborhood and school could not be estimated. We specified neighborhood rather than school at Level 3 because of the larger number of neighborhoods than schools, because neighborhoods were largely nested within schools (in that adolescents from several neighborhoods attended the same school) and because there was significant variance in adolescent alcohol misuse between neighborhoods (intraclass correlation coefficient [ICC] = .003, $p < .05$) but not schools (ICC = .001, $p = .18$).

The data were arranged in a cohort sequential design whereby data collected over approximately 2.5 years from three cohorts (i.e., cohorts enrolled at Grades 6, 7, and 8) were merged to allow accelerated trajectories of alcohol misuse to be modeled over approximately 6 years. We used age to measure the passage of time, thereby allowing change in alcohol misuse to be modeled from age 11 through age 17 (Mehta & West, 2000; Miyazaki & Raudenbush, 2000).

We report the analysis in stages beginning with estimation of the unconditional model to determine the random components and form of the trajectory, with an a priori expectation of a linear model. We then tested the cohort sequential design assumption of no differences across the three cohorts in the association between age and alcohol misuse by using a likelihood ratio test to compare the unconditional model to a model that added a variable measuring cohort and the interaction between cohort and age (Miyazaki & Raudenbush, 2000). A nonsignificant result would suggest the appropriateness of merging data across cohorts.

We next estimated a series of conditional models, using the concepts of micro-, exo-, and mesosystems to guide model building. All models controlled for the demographic variables and, due to multicollinearity, did not include the school context measure of stress. Model 1, the microsystem model, included the three sets of variables describing the family, peer, and school contexts. The variable sets included the main effects of the four attributes in each context and the two-way within-context interactions between alcohol modeling and closeness, social regulation, and stress. Model 2, the exosystem model, added to this microsystem model the set of neighborhood variables and their within-context interactions. Three mesosystem models then added to the exosystem model the two-way between-context interactions between alcohol modeling in one context, and closeness, social regulation, and stressful relations in the other context for the family and peer contexts (Model 3), family and school contexts (Model 4), and peer and school contexts (Model 5). We constructed the interactions such that, in Models 3 and 4, family characteristics moderated the relationships between adolescent alcohol misuse and peer/school alcohol modeling (e.g., family closeness moderated the relationship between adolescent and friends' alcohol misuse), and in Model 5, peer characteristics moderated the relationship between adolescent alcohol misuse and school alcohol modeling. We also included the between-context interaction between the two indicators of alcohol modeling because of the risk associated with accumulated exposure (Ary, Tildesley, Hops, & Andrews, 1993).

For each conditional model, we report the set of coefficients for the fixed effects of the social context attributes and the two-way interactions between context attributes. We also report the *F* statistic for testing the significance of the set of variables added to each successive model. Because the social context variables were time varying, a significant effect means that the relationship between the social context variable (or interaction between context variables) and adolescent alcohol misuse was significant on average over the ages examined. For ease of interpretation, we refer throughout to each contextual attribute by the construct name (e.g., peer stress) rather than the specific indicator (e.g., intransitive friendships triads). Significant interactions were probed by plotting the regression of alcohol misuse on alcohol user models at values of the moderator variable set at the mean and 1 *SD* above and below the mean (Curran, Bauer, & Willoughby, 2004).

All analyses were conducted using SAS version 9.1.3., using PROC MIXED and PROC MIANALYZE to estimate the unconditional and conditional mixed models (SAS, 2002–2003).

Results

Unconditional Model

A linear model with two random components, the individual and neighborhood intercepts, demonstrated significant individual (Z score = 42.06, $p < .0001$) and between-neighborhood (Z score = 2.96, $p < .001$) variation around the mean intercept for alcohol use centered at age 12. Linear models that included a random slope at the individual and neighborhood levels or at the individual level could not be estimated. The model also showed significant fixed effects such that the mean intercept for alcohol misuse was significantly different from zero ($B = -.02$, $SE = .01$, $p < .05$) and there was significant linear growth in the mean slope ($B = .10$, $SE = .00$, $p < .0001$) through age 17.

We compared this model to quadratic, unstructured, and spline models, each of which also included random intercepts at the individual and neighborhood levels. Based on the Bayesian information criterion (BIC) fit statistic, with smaller values by three points or more indicating better fit (Raftery, 1995), the linear model was favored over either the quadratic or the unstructured model (linear BIC = 45,570; quadratic BIC = 45,573; unstructured BIC = 45,615). Although the difference between the BICs for the linear and quadratic models was 3 points, the fixed quadratic effect was not significant and the likelihood ratio test comparing the two models was not significant. The spline model did not demonstrate sufficient improvement in model fit (BIC = 45,568) to be selected.

Test of Cohort Differences

The likelihood ratio test comparing linear models with and without the addition of a cohort variable and cohort by age interaction term was not statistically significant, indicating a lack of cohort effects and the appropriateness of the cohort sequential design.

Conditional Models

Demographic variables. We first examined the contributions of the demographic variables to adolescent alcohol misuse. The positive linear effect of age on alcohol misuse was significant after controlling for the other demographic variables ($B = .10$, $SE = .01$, $p < .0001$). High school enrollment, the other time-varying demographic characteristic, was significantly positively associated with alcohol misuse trajectories ($B = .05$, $SE = .01$, $p < .0001$). For the time-invariant variables, we examined the effects of the variables on the intercept and slope of the trajectories. Initial levels of alcohol misuse were higher only for youth whose parents had lower rather than higher educational levels ($B = .05$, $SE = .02$, $p < .05$). The rate of change in alcohol misuse was slower for Black youth compared with White youth ($B = -.06$, $SE = .01$, $p < .0001$) and faster for youth in families without two parents ($B = .04$, $SE = .01$, $p < .01$).

Microsystem model. Results of the microsystem, exosystem, and mesosystem models are shown in Table 1. For the microsystem model, after adjusting for the demographic variables and all other variables in the model, all the family context variables and the two-way interactions between family alcohol use modeling and family social bond indicators were significantly associated with alcohol misuse from ages 11 through 17. As expected, the indicators of family closeness and social regulation were negatively associated with adolescent alcohol misuse, whereas family stress and family alcohol use were positively associated with adolescent behavior. As hypothesized, family closeness ($p < .10$) and social regulation buffered the effect of family alcohol modeling on adolescent alcohol misuse, whereas family stress magnified the effect.

In the peer context, only the two-way interaction between peer social regulation and peer modeling of alcohol use was significant. In an unexpected finding, peer modeling of alcohol use was negatively associated with adolescent alcohol misuse, but greater social regulation buffered the negative effect. (The bivariate association between peer modeling of alcohol use and adolescent alcohol misuse was positive, as expected.) In the school context, alcohol modeling by all students was significantly positively associated with adolescent alcohol misuse; none of the social control variables were significantly associated with adolescent alcohol misuse.

Exosystem model. With the addition of the set of neighborhood variables to the microsystem model, neighbors' alcohol misuse had a significant positive effect on adolescent alcohol misuse. No other predictors or any of the interaction terms was significant. The effects of the family, peer, and school variables remained unchanged except that the interaction between peer stress and peer modeling of use became statistically significant. The negative (protective) effect of peer modeling was attenuated by higher stress.

Mesosystem models. For all three mesosystem models, the sets of Family × Peers, Family × School, and Peers × School interactions were significant additions to the exosystem model. In the Family × Peers and Family × School models, family social regulation buffered effects of both friends' and schoolmates'

alcohol misuse. In addition, both family stress and family alcohol use significantly magnified effects of both friends' and schoolmates' alcohol misuse. In the Peers × School model, peer regulation ($p < .10$) and peer alcohol misuse enhanced effects of schoolmates' modeling of alcohol use.

Discussion

Consistent with Bronfenbrenner's ecological perspective on the importance of the multiple social contexts in which lives are embedded, attributes of family, peer, school, and neighborhood contexts uniquely predicted development of adolescent alcohol misuse from age 11 through age 17. The presence of multiple within-context and between-contexts interactions involving constructs from social learning and social control theories largely affirmed Bronfenbrenner's prediction that interactions rather than main effects will be the principal effects demonstrated in ecological research. In addition, our findings partially confirmed our specific expectation that the nature of moderation involving closeness and social regulation would vary depending on whether peers or adults were the referent, whereas stress would always exacerbate alcohol modeling effects. Overall, our findings suggest the appropriateness of an ecological approach for examining adolescent alcohol misuse and support the need, as noted elsewhere (Cook, 2003), to draw on theory to specify the contextual attributes and joint effects examined.

We consider first the within-context findings from the family, peer, school, and neighborhood contexts in the microsystem and exosystem models. In the family and peer contexts, relationships between modeling of alcohol use by others and adolescent alcohol misuse were always moderated by the nature of social bonds. Thus, the social learning effects of modeling could not be estimated in absence of consideration of the quality of relationships. Similarly, effects of relationship attributes identified by social control theory could not be described without reference to alcohol modeling. In addition to this predominance of interactions over main effects, the nature of interactions involving family characteristics was as hypothesized. Parental supervision and adolescent–parent closeness (marginal effect) buffered alcohol modeling effects in the family, whereas family stress exacerbated family alcohol modeling effects. Several previous studies of interactions between family characteristics and family alcohol use found support for mitigating effects of a positive family environment on parent alcohol use (M. P. Farrell et al., 1995; Urberg et al., 2005; Zhang, Welte, & Wieczorek, 1999). Although most prior studies focused on parent–child closeness, our findings extend the buffering effects of parenting to the supervisory domain. Parental supervision and monitoring typically have been examined only as main effects on adolescent alcohol and other substance use.

Two interactions between alcohol modeling and the social control variables characterized the peer context: Peer Alcohol Modeling × Peer Social Regulation and Peer Alcohol Modeling × Peer Stress. In an odd finding, modeling of alcohol misuse by friends was negatively related to alcohol misuse. The interactions were such that at higher levels of peer alcohol use, peer social regulation and peer stress lessened the negative modeling effect. The interactions can be interpreted as consistent with the hypothesized direction of peer effects, in that the risk for alcohol use was increased for youth exposed to higher levels of peer alcohol use and higher social regulation or higher stress compared to those exposed to higher levels of peer alcohol use and lower social regulation or lower stress. Even so, the overall negative effect of peer alcohol use (not present in bivariate analyses), although small, was opposite all expectations and evidently due to the presence of other variables.

In contrast to the family and peer findings, in the school and neighborhood contexts, no significant joint effects of social learning and social bond variables were found. Instead, alcohol modeling by others, whether schoolmates or other adolescents in the neighborhood, was the only significant predictor. It is noteworthy that these modeling effects were detected even after adjusting for friends' modeling of alcohol use. These findings extend the consistently reported association between adolescent and friends' alcohol use to other peer contexts. An implication is that although immediate friendships are central to adolescent alcohol use, the larger and more inclusive school-wide and neighborhood peer environments also clearly matter.

In the mesosystem models, most of the between-context interactions involving characteristics of family and peers, family and school, and peers and school were significant. The expected reverse relationships, depending on whether the family or peers were considered, between social regulation and modeling of alcohol misuse were found. That is, family social regulation buffered effects on adolescent alcohol misuse of alcohol modeling by the adolescent's friends and schoolmates, whereas peer social regulation amplified the modeling effects of alcohol misuse by schoolmates ($p < .10$). The family findings are consistent with studies suggesting that a positive family environment, as indicated by both closeness and supervision, can mitigate negative peer effects (Brook et al., 1986; Brook et al., 1990; Marshal & Chassin, 2000). In addition, and not typically the focus of prior studies, our findings show that the family can amplify negative peer modeling both through family stress (conflict) and through family alcohol use.

Although prior studies of family moderating effects are relatively few, several studies have examined mediation of family alcohol socialization factors. In particular, weak family bonds, as indicated by measures of closeness and supervision, have been shown to lead to association with substance-using peers and then to adolescent use (e.g., Kandel & Andrews, 1987; Simons-Morton & Chen, 2005). Given our conditional effects and those prior mediational findings, perhaps models of moderated mediation should be investigated (Muller, Judd, & Yzerbyt, 2005). That is, investigation could examine whether indirect effects on alcohol misuse of parenting characteristics through peer factors are moderated by attributes of other social contexts. The possibility of moderated mediation indicates the complexity of social contextual relationships and the need for research testing expanded models of relationships among contextual factors. An implication of our findings is that consideration of contingencies in contextual relationship should not be discounted in favor of examining only main effects or mediated relationships.

Taken together, our findings indicate that attributes of all social contexts are relevant to development of adolescent alcohol misuse. Although all contexts were implicated in adolescent alcohol use, the family context emerged as perhaps most important in that all characteristics were associated with adolescent alcohol misuse. As well, all between-context interactions involving the family predicted adolescent alcohol misuse. In contrast to the perception that family influence wanes over adolescence, our findings suggest the enduring influence of the family throughout the adolescent age span examined.

Our findings also indicate the relevance of both social learning and social control theories to adolescent alcohol misuse. Although interrelations between social learning and social control variables generally played out as expected, it is surprising that only the social learning theory variable of alcohol modeling was a significant factor in the school and neighborhood contexts. Perhaps in these more distal, less intimate environments compared to family and friendship groups, adolescents attend to what is most obviously seen—in this case, the alcohol use behavior of others. In addition, or alternatively, perhaps the level of alcohol misuse in this sample was not sufficiently serious to be sensitive to school or neighborhood social controls.

Our analyses are intended to be a specific empirical assessment of Bronfenbrenner's far-reaching perspective on the ecology of human development. The strength of our analyses rests to a great extent in our use of contextual measures that for the most part were constructed independent of our adolescent respondents. Only the measures of the family context and measure of the relationship closure in the peer context were based on adolescent reports. Use of social network analysis allowed us to operationalize peer and school context relational measures with a method specifically intended for measuring relationships. Moreover, due to the data requirements of social network analysis, the measures of the alcohol misuse of friends, schoolmates, and neighbors were based on aggregated self-reports rather than adolescent perceptions. Use of self-reports avoided the bias due to projection effects when adolescent perceptions are used to measure the alcohol use behavior of others (Bauman & Ennett, 1996). At the neighborhood level, our use of parent data and linkage of respondents to census block groups provided measures of social processes in neighborhoods based on multiple informants. The strength of the measures provides reassurance that where expected relationships were not found, the cause is not likely due to inadequate measurement.

Other strengths of our study in the match of methods to Bronfenbrenner's conceptualization of development in context are the application of multilevel modeling to accommodate nested data, examination of developmental trajectories, and use of time-varying measures of the social context variables.

Our study has methodological limitations. Although our analysis of time-varying measures demonstrated that the contribution of social context characteristics to alcohol misuse averaged across all ages examined, we did not test differences at each age in the relationships between the social context variables and the alcohol misuse. Another shortcoming is that our statistical models, although based on longitudinal data, did not allow us to assess temporality of relationships. The models assessed the contemporaneous relationships between the time-varying social context measures and alcohol misuse at each time point assessed (modeled as age); the models did not assess whether the social context attributes at earlier ages predicted alcohol misuse at subsequent ages after controlling for prior involvement. Other statistical models (e.g., autoregressive latent trajectory models) are needed to conduct these analyses and are an essential consideration for future research.

The limitation concerning temporality is most costly in the peer context where we cannot determine whether the relationship between adolescent alcohol misuse and friends' drinking is due to the adolescent's selection of friends or to socialization by those friends. Prior research suggests that both selection and socialization are likely at work (Bauman & Ennett, 1996); indeed, the prediction from Bronfenbrenner's perspective would be that reciprocal processes exist between adolescents and peers. The question is made more complicated by the unexpected negative relationship found in our multivariable models between adolescent alcohol use and friends' alcohol use, although we note that the bivariate relationship was positive. Determining directionality in the family context is also problematic in that adolescent drinking could shape parenting practices or be a cause of family conflict (Ennett, Bauman, Foshee, Pemberton, & Hicks, 2001). Moreover, adolescents could cause their parents' drinking. At the school and neighborhood levels, directionality may flow less ambiguously from the context to the adolescent, although selection by parents into schools and neighborhoods cannot be discounted. With that caveat, our findings contribute to the literature on peer influences on adolescent drinking because exposure to peers' alcohol use at school and in the neighborhood predicted adolescent alcohol misuse net of demographic and family factors, close friends' alcohol misuse, and all other contextual variables.

Besides methodological limitations, our application of Bronfenbrenner's ecology of human development perspective is incomplete in several ways. Perhaps most important is that we did not examine reciprocity between adolescents and their social contexts. As well, we did not assess the influence on adolescent development of the macrosystem, or cultural factors. It is possible that the relationships obtained varied by the race/ethnicity or gender of the respondents or would vary compared to youth in other countries in cross-cultural comparisons. These are areas for future research.

Despite limitations, our study addresses challenges to contextual research in our use of theory to identify specific attributes of contexts and contextual interdependencies for examination. Our findings affirm Bronfenbrenner's social ecological perspective in demonstrating that adolescent alcohol misuse is a socially conditioned behavior. Our findings also affirm the joint relevance of social learning and social control theories in that effects of alcohol use by others were often, although not always, conditional on the nature of social bond. Taken together, our findings support the generality that family, peer, school, and neighborhood social contexts and interdependencies within and between social contexts are significantly implicated in adolescent alcohol misuse.

Trumping Shame by Blasts of Noise: Narcissism, Self-Esteem, Shame, and Aggression in Young Adolescents

This experiment tested how self-views influence shame-induced aggression. One hundred and sixty-three young adolescents (M = 12.2 years) completed measures of narcissism and self-esteem. They lost to an ostensible opponent on a competitive task. In the shame condition, they were told that their opponent was bad, and they saw their own name at the bottom of a ranking list. In the control condition, they were told nothing about their opponent and did not see a ranking list. Next, participants could blast their opponent with noise (aggression measure). As expected, narcissistic children were more aggressive than others, but only after they had been shamed. Low self-esteem did not lead to aggression. In fact, narcissism in combination with high self-esteem led to exceptionally high aggression.

Violent aggressive behavior in youth leaves scars on perpetrators, victims, and society at large. Among the many factors that contribute to youth aggression, the self-regard of perpetrators has been a theoretically important but empirically controversial cause. For many years, the prevailing view has held that aggressive youth have low self-esteem (e.g., California Task Force to Promote Self-Esteem and Personal and Social Responsibility, 1990; Carr, 1999; Heide, 1997; Kaplan, 1975; Keith, 1984; Willock, 1987). Applied and practical efforts have also focused on low self-esteem as a cause of violence. For example, following a series of incidents in which schoolchildren fired guns and killed their classmates at various American schools, several organizations (including the U.S. Department of Education) prepared lists of alleged warning signals to be used to identify youth who might be relatively likely to engage in such destructive violence, and nearly all the lists included low self-esteem as a significant risk factor (e.g., Lord, 1999).

Despite this apparent consensus, no compelling theoretical rationale existed to explain why low self-esteem would cause aggression. Even more problematic, a persuasive body of empirical evidence was lacking. Although there have been a few exceptions (Lochman & Dodge, 1994), most studies involving elementary school-aged children found no concurrent or prospective links between low self-esteem and aggression (Gresham, MacMillan, Bocian, Ward, & Forness, 1998; Hymel, Rubin, Rowden, & LeMare, 1990; Kupersmidt & Patterson, 1991). In fact, several studies found that aggressive children have inflated rather than deflated self-views (Brendgen, Vitaro, Turgeon, Poulin, & Wanner, 2004; David & Kistner, 2000; Zakriski & Coie, 1996) and that high self-esteem is a risk factor for exacerbating aggression problems over time (Menon et al., 2007).

One possible explanation of these findings is that low self-esteem may only cause aggression in adolescents because they are more concerned than younger children about maintaining desired self-images (Harter, 2006; Rosenberg, 1986). Contrary to that reasoning, however, the bulk of studies involving adolescents also found no link between low self-esteem and aggression (East & Rook, 1992; Esposito, Kobak, & Little, 2005; Olweus, 1994; Prinstein, Boergers, & Vernberg, 2001; Salmivalli, Kaukiainen, Kaistaniemi, & Lagerspetz, 1999; but see Donnellan, Trzesniewski, Robins, Moffitt, & Caspi, 2005, for an exception). As it

stands, there is little reason to adhere to the view that low self-esteem causes aggressive behavior in youth.

Narcissism and Aggression

In a comprehensive literature review, Baumeister, Smart, and Boden (1996) rejected the view that low self-esteem causes aggression. They proposed instead that violence most commonly occurs when inflated views of self and unstable beliefs in personal superiority are threatened. These conceptions of excessive self-love are relevant to narcissism, a term that comes from the Greek myth about a handsome young man who falls in love with his own reflection in the water. In its extreme form, narcissism is a personality disorder that involves grandiose views of self, an inflated sense of entitlement, and exploitative attitudes toward others (American Psychiatric Association, 1994). Most current psychological research focuses on "normal narcissism," operationalized as a trait on which people in the general population vary (Morf & Rhodewalt, 2001; Raskin & Terry, 1988). Intuition suggests that narcissism is equivalent to excessively high self-esteem, but research showed that narcissism and self-esteem are not strongly correlated (Brown & Zeigler-Hill, 2004). Narcissists are self-absorbed and arrogant, but they differ in feelings of self-assurance and sufficiency (reflecting higher levels of self-esteem) or self-doubt and insufficiency (reflecting lower levels of self-esteem; Cain, Pincus, & Ansell, 2007; Dickinson & Pincus, 2003; Rose, 2002; Wink, 1991).

The link between narcissism and aggression has been firmly established in adults (e.g., Bushman & Baumeister, 1998; Bushman, Bonacci, van Dijk, & Baumeister, 2003; Donnellan et al., 2005; Stucke & Sporer, 2002; Twenge & Campbell, 2003). Preliminary evidence suggests that narcissists with high self-esteem are particularly prone to behave aggressively (Papps & O'Carroll, 1998; Wink, 1991). Unfortunately, few studies have examined the effects of narcissism and self-esteem on aggression in youth. This lack of emphasis is surprising because childhood is the time when the foundation for lifelong aggressive or nonaggressive behavior styles is laid (e.g., Loeber & Hay, 1997). For both clinical and theoretical reasons, it is important to study the psychological mechanisms underlying aggressive inclinations at a time that they unfold. One cause of the paucity of research on narcissistic aggression in youth has been the absence, until recently, of a scale designed to measure early manifestations of narcissism. Recent developments indicate, however, that the construct of narcissism can be reliably identified and distinguished from related personality dimensions in older children and adolescents (C. T. Barry, Frick, & Killian, 2003; Frick, Bodin, & Barry, 2000). We recently developed the Childhood Narcissism Scale, a reliable and valid measure of narcissistic traits in normal child and adolescent populations (Thomaes, Stegge, Bushman, Olthof, & Denissen, 2008).

Shame-Induced Aggression

Violence and aggression often occur when an individual's pride, reputation, or self-esteem has been impugned or threatened. In late childhood and adolescence, such situations are typically experienced as shameful (Nishina & Juvonen, 2005; Olthof, Ferguson, Bloemers, & Deij, 2004; Reimer, 1996). Shameful events often involve the public exposure of some failure or shortcoming (Olthof, Schouten, Kuiper, Stegge, & Jennekens-Schinkel, 2000; Smith, Webster, Parrott, & Eyre, 2002). When shamed, people are painfully aware that others might think they are flawed (Lewis, 1971; Tangney & Dearing, 2002). Importantly, this awareness of others' disapproval is easily internalized as a global condemnation of the self (e.g., "I am a bad and worthless person"). Over the course of late childhood, such self-condemning negative self-appraisals become a more pronounced part of the shame experience (Ferguson, Stegge, & Damhuis, 1991). Gradually, shameful events come to constitute a more serious threat to self-esteem.

How do people behave when they are shamed? Shameful events may cause people to withdraw and hide from social contact (e.g., Lindsay-Hartz, De Rivera, & Mascolo, 1995). Alternatively, shameful events may cause people to lash out aggressively against others. Across the life span, shame-prone individuals are predisposed to externalize blame, to feel anger, and to behave aggressively (Tangney, Wagner, Hill-Barlow, Marschall, & Gramzow, 1996). Situationally induced shame produces similar reactions (Bennett, Sullivan, & Lewis, 2005; Thomaes, Stegge, & Olthof, 2005). Shame-induced aggression may serve an ego-protective function (Tangney & Dearing, 2002). By directing blame and anger on others, people can prevent their self-esteem from (further) damage. Aggression shifts attention away from painful awareness of a devalued self. Also, by asserting the dominant aggressive stance, people can reaffirm the self and "save face" in front of others. In summary, shame-induced aggression may originate from the basic human motive to preserve self-esteem.

Self-Views and Shame-Induced Aggression

If the traditional view that low self-esteem causes aggression is true, one would predict that youth with low self-esteem should be particularly aggressive when shamed because shameful events make them feel even more inferior. This prediction, however, is inconsistent with what we know about the motivations that surround self-esteem. Self-verification theory holds that people generally try to maintain consistent self-appraisals and dislike changing their self-views (Swann & Read, 1981). From this perspective, youth with low self-esteem should be relatively untouched by shameful events because their habitual self-appraisals are already low. In contrast, youth with inflated narcissistic self-views should be more vulnerable than others to shameful events because they are highly motivated to protect their inflated self from being damaged. Indeed, vulnerability to shame has been described as a key component of narcissism (Morrison, 1989; Tracy & Robins, 2004). These notions are consistent with the empirical findings in adult samples showing that narcissists are aggressive following ego threat.

Present Experiment

A between-subjects experimental design was used to examine how self-views influence aggressive responses to induced shame. Participants were 10–13 years old. From several developmental perspectives, this is an ideal age period for the purposes of this experiment. First, in early adolescence, shame is both a frequent and an aversive emotional experience due to developmental increases in self-consciousness (Ryan & Kuczkowski, 1994; Simmons, Rosenberg, & Rosenberg, 1973), the ability to view the self from others' perspective (Harter, 2006), and the ability to make global negative evaluations of the self (Ferguson et al., 1991). Second, early adolescence is a time when children become increasingly concerned about maintaining worth and approval, and self-protective motives come to exert a stronger influence on their behavior (Harter, 2006; Rosenberg, 1986). Third, early adolescence is an ideal time to measure childhood narcissism. Young children typically hold unrealistically positive self-views because they lack the abilities to differentiate their actual self from their ideal self and to base their self-views on social comparisons (Harter, 2006). By age 10, most youth have overgrown age-normative overestimation of competence that likely is a prerequisite for the meaningful assessment of individual differences in childhood narcissism (Thomaes et al., 2008). Fourth, early adolescence is a time when children's self-views are still relatively malleable before they become crystallized in late adolescence and adulthood (Trzesniewski, Donnellan, & Robins, 2003). Thus, early adolescence may be a critical age period to initiate aggression interventions targeted at changing self-views. This experiment tested whether a link between self-views and aggression has already been established by then.

Aggressive behavior was examined in a *situational context* of shame. We did not address how *felt* shame was involved in youth's aggressive behavior. Several authors have noted that although feelings of shame may mediate shame-induced aggression, these feelings are not necessarily consciously experienced (e.g., Lewis, 1971; Robins, Tracy, & Shaver, 2001). For conceptual clarity, we chose to focus on shame-induced aggression on a situational level.

We used a shame manipulation based on the easy task failure paradigm (e.g., Lewis, Alessandri, & Sullivan, 1992). People who fail an easy task are especially likely to experience shame. Participants in our experiment failed a competitive reaction time task. They were randomly assigned to shame or no-shame control conditions. Participants in the shame condition were told that their opponent was one of the slowest contestants tested so far, and they saw their own name at the bottom of a ranking list posted on the bogus FastKid! Web page (below their opponent's name). The Internet rankings highlighted public exposure, which should enhance feelings of shame (Smith et al., 2002). Participants in the control condition were told nothing about their opponent's abilities and did not see the bogus Web page. A validation study showed this shame manipulation to be highly effective (Thomaes et al., 2005). The shame condition elicits feelings of shame in young adolescents, whereas the control condition does not. Next, participants were given a chance to blast their opponent with loud noise through headphones (the aggression measure). We predicted that narcissistic youth would behave most aggressively, but only in the shame condition. We did not predict high levels of aggression in youth with low self-esteem. On the contrary, on the basis of prior research, we predicted that high self-esteem would enhance narcissistic aggression (Papps & O'Carroll, 1998; Wink, 1991).

Method

Participants

Participants were 163 young adolescents (54% boys) from two public middle schools serving middle- and upper-middle-class neighborhoods in southeastern Michigan. In the school district, 8% of students are eligible for reduced-price lunch programs. Participants ranged in age from 10 to 13 years ($M = 12.2$, $SD = 0.6$). Almost all were Caucasians (96%). To participate, adolescents received informed parental consent (29% of parents consented) and gave their own assent (98% of adolescents assented). Participants received a small gift (e.g., mechanical pens, markers) in exchange for their voluntary participation.

Self-View Questionnaire

A few weeks prior to the experiment ($M = 3$ weeks, range = 1–5 weeks), participants completed self-report measures of narcissism and self-esteem at their school. Narcissism was measured using the reliable and valid Childhood Narcissism Scale (Thomaes et al., 2008). This 10-item scale assesses grandiose views of self, inflated feelings of superiority and entitlement, and exploitative interpersonal attitudes. Sample items include "Without me, our class would be much less fun," "Kids like me deserve something extra," and "I often succeed in getting admiration." Items are rated along a 4-point scale ranging from 0 (*not at all true*) to 3 (*completely true*). Responses were summed, with higher scores indicating higher levels of narcissism. In the present experiment, the alpha coefficient for the scale was .76.

Self-esteem was measured using the 6-item *global self-worth* subscale of the Self-Perception Profile for Children (Harter, 1985). This scale assesses the extent to which participants are satisfied with themselves and the way they are leading their lives. Sample items include "Some kids like the kind of person they are" and "Some kids are not very happy with the way they do a lot of things." Following others (e.g., Brendgen et al., 2004), we used a 4-point scale response format ranging from 0 (*I am not like these kids at all*) to 3 (*I am exactly like these kids*). After reverse scoring negatively worded items, responses were summed, with higher scores indicating higher levels of self-esteem. The alpha coefficient for the scale was .72.

Procedure

Participants were tested individually in a quiet room at their school. They were told that they would be competing on an Internet reaction time game called FastKid! against an opponent of the same sex and age from a school in Columbus, OH. In reality, there was no opponent and the computer controlled all events. Participants were told that FastKid! consisted of two 5-trial rounds, each with a bonus. The first-round bonus was the ability to send a written message to the opponent. The second-round bonus was the ability to blast the opponent with loud white noise (sounds like radio static) through headphones after winning a trial. Through a rigged lottery, the opponent had the bonus in the first round, whereas the participant had the bonus in the second round. Participants were given samples of noise they could set for their opponent. The noise levels ranged from 55 (Level 1) to 100 dB (Level 10) in 5-dB increments. The maximum noise level, 100 dB, is about the same intensity as a smoke alarm. A nonaggressive no-noise setting (Level 0) was also included.

Participants were randomly assigned to shame or no-shame control conditions. In the shame condition, participants were told that they were lucky to compete against one of the worst players thus far. The experimenter then logged onto the fictitious FastKid! Web site and showed participants their opponent's name at the bottom of the ranking list. The experimenter said, "This means you should win easily!" Participants were told that immediately after the first round of the game, new rankings would appear on the very popular FastKid! Web site and that their own name would be included in those rankings. After competing with the opponent on the first five reaction time trials, a message appeared on screen that said, "Sorry (participant's name), you lost!" The opponent then sent the participant a message that said, "Can't wait to see the rankings!" Then, the new rankings showed the participant's name at the bottom of the list, beneath the opponent's name. The control condition was similar to the shame condition, with three exceptions. First, participants received no information about how good their opponent was (and saw no rankings on the Web site before the game). Second, participants saw no rankings after the game. Third, the opponent's message said, "Huh?! Is the first round finished already?" We used a losing control condition because we wanted to test the effects of shame above and beyond the effects of mere disappointment or frustration from losing a game.

In the second round of the game, participants had the "noise bonus," so they could blast their opponent with loud noise after winning a trial. Prior to each of the five trials of Round 2, participants set the noise level their opponent would receive if the opponent lost. After each trial, participants were informed whether they had won (i.e., Trials 1, 2, 4, and 5) or lost (i.e., Trial 3) that trial. To obtain an aggression measure unconfounded by the (nonmanipulation) effect of losing Trial 3, the average level of noise set for the opponent across the first three trials was used to measure aggression. The alpha coefficient for the aggression measure was .85. Finally, participants were thoroughly debriefed to remove lingering effects of the manipulations and were given a small gift.

Results

Preliminary Analyses

Sex differences and age. Boys were significantly more aggressive than girls, $F(1, 161) = 8.37, p < .01, d = 0.45$. Aggression was not affected by age, $t(161) = -0.33, p > .74, b = -0.07, \beta = -.03$. Because there were also no interactions involving sex or age, the data from boys and girls of different ages were combined for subsequent analyses.

Equivalence of experimental conditions. Narcissism and self-esteem scores did not differ in the shame and no-shame groups ($ps > .30$). Thus, random assignment to conditions was effective. Narcissism and self-esteem were only weakly correlated ($r = .09$).

Primary Analyses

Table 1 contains the descriptive statistics for the experiment. Data were analyzed using hierarchical multiple regression analysis. The dependent variable was aggressive behavior, defined as the average intensity of noise participants gave their ostensible opponent. The main effects for condition, narcissism, and self-esteem were entered in Step 1; the two-way interactions involving these variables were entered in Step 2; and the three-way interaction was entered in Step 3. Narcissism and self-esteem scores were centered to reduce multicollinearity (Aiken & West, 1991; Jaccard & Turrisi, 2003). A maximum variance inflation factor (VIF) greater than 10 indicates that multicollinearity may be unduly influencing the least squares estimates (e.g., Neter, Wasserman, & Kutner, 1990). The maximum VIF in the regression analysis was 3.26, indicating that multicollinearity was not a problem.

Table 1

Means and Standard Deviations in the Shame and No-Shame Control Conditions

		Shame (N = 83)	Control (N = 80)
	Range	M (SD)	M (SD)
Narcissism	2–26	12.04 (4.32)	11.29 (4.92)
Self-esteem	3–18	13.60 (2.89)	13.51 (3.38)
Aggression	1–10	7.06 (2.51)	7.02 (2.66)
Age (months)	131–166	146 (8)	146 (8)

The analysis revealed a main effect for narcissism, $t(159) = 2.01, p < .05, b = 0.41, \beta = .16$. This main effect, however, was qualified by a significant interaction between narcissism and condition, $t(156) = 2.03, p < .05, b = 0.82, \beta = .21$ (see Figure 1). As expected, narcissism was positively related to aggression when participants were shamed, $t(81) = 2.91, p < .01, b = 0.89, \beta = .31$. Narcissism was not related to aggression when participants were not shamed, $t(78) = 0.04, p > .96, b = 0.01, \beta = .01$.

Although self-esteem did not directly influence aggression levels, on the basis of prior research, we anticipated that narcissism in combination with high self-esteem would lead to exceptionally high levels of aggression in the shame condition (Papps & O'Carroll, 1998; Wink, 1991). As expected, there was a significant Narcissism × Self-Esteem × Condition interaction, $t(155) = 2.00, p < .05, b = 0.84, \beta = .19$. To interpret the three-way interaction, we examined the two-way interactions between narcissism and self-esteem separately for the shame and no-shame control conditions. As expected, narcissism and self-esteem interacted to influence aggression in the shame condition, $t(79) = 2.65, p < .01, b = 0.91, \beta = .28$ (see Figure 2; high values of narcissism and self-esteem were 1 SD above the mean and low values were 1 SD below the mean; Aiken & West, 1991). Figure 2 shows that narcissism and aggression were

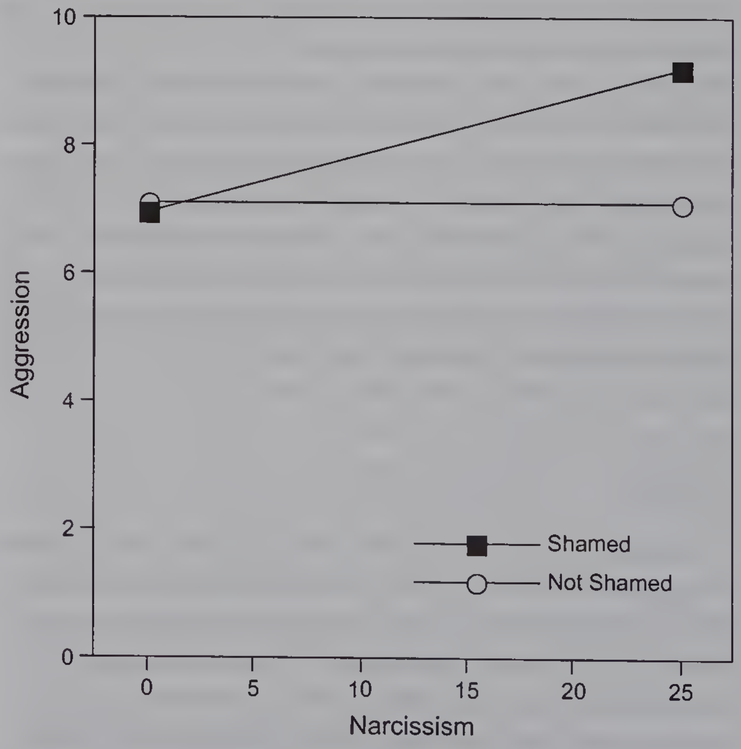

Figure 1. Relationship between narcissism and aggression for participants in the shame and the no-shame control conditions.

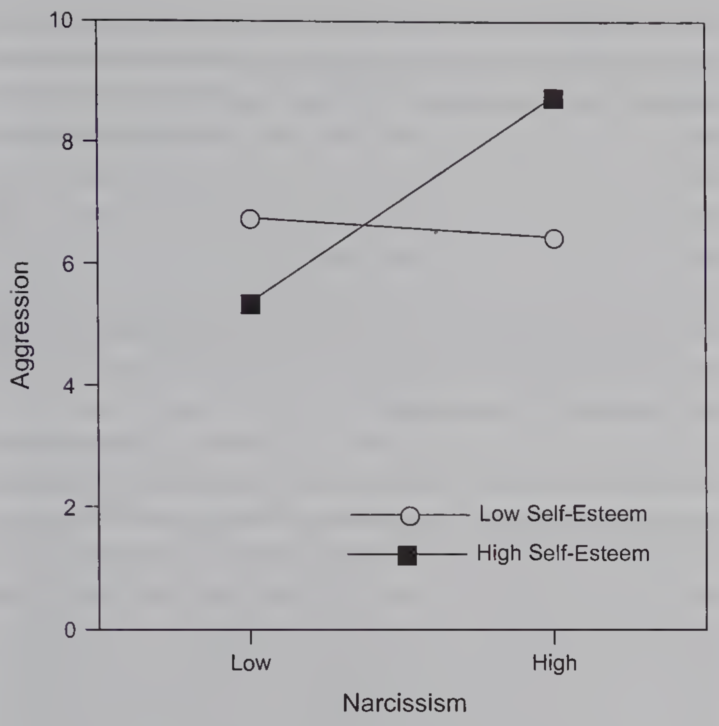

Figure 2. Relationship between narcissism and aggression for participants with high and low self-esteem in the shame condition.
Note. High values of narcissism and self-esteem are 1 *SD* above the mean; low values of narcissism and self-esteem are 1 *SD* below the mean.

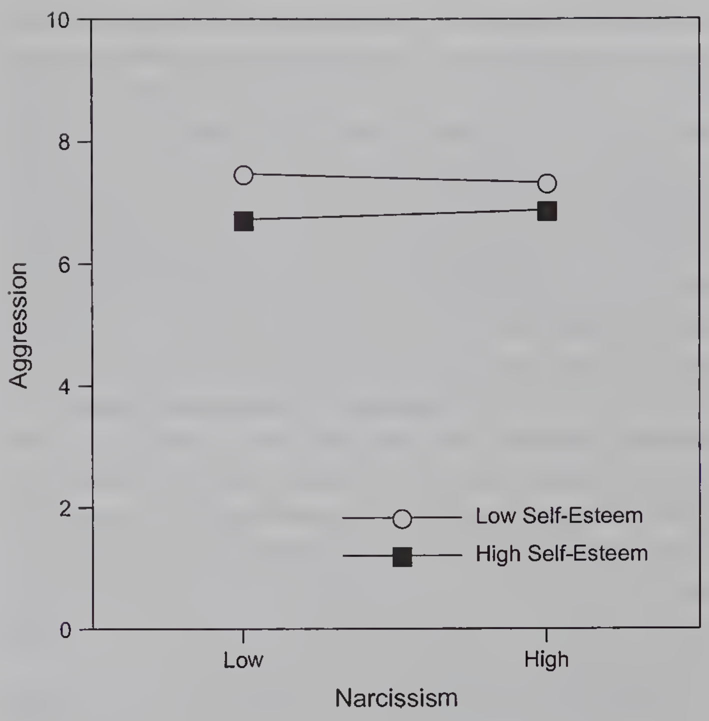

Figure 3. Relationship between narcissism and aggression for participants with high and low self-esteem in the no-shame control condition.
Note. High values of narcissism and self-esteem are 1 *SD* above the mean; low values of narcissism and self-esteem are 1 *SD* below the mean.

strongly associated in shamed youth with high self-esteem, $t(79) = 4.00, p < .001, b = 1.69, \beta = .59$. In contrast, narcissism and aggression were not associated in shamed youth with low self-esteem, $t(79) = -0.29, p > .77, b = -0.14, \beta = -.05$. As expected, narcissism and self-esteem did not interact to influence aggression in the no-shame control condition, $t(76) = 0.30, p > .76, b = 0.07, \beta = .04$. As shown in Figure 3, narcissism and aggression were not associated in nonshamed youth with high or low self-esteem, $t(76) = 0.24, p > .81, b = 0.09, \beta = .04$ and $t(76) = -0.17, p > .86, b = -0.06, \beta = -.03$, respectively.

Discussion

The present experiment examined how narcissism and self-esteem influence young adolescents' shame-induced aggressive behavior. As predicted, narcissistic youth were more aggressive than others, but only after they had been shamed. Narcissists seem highly motivated to create and maintain a grandiose view of self. They tend to interpret social situations in terms of how they reflect on the self, and they engage in self-regulatory strategies to protect self-esteem when they need to (Morf & Rhodewalt, 2001). As shameful situations constitute a threat to grandiosity, narcissistic shame-induced aggression can likely be viewed as defensive effort to maintain self-worth.

No support was found for the traditional view that low self-esteem underlies aggression. In fact, that view was contradicted by the finding that high self-esteem (not low self-esteem) increased narcissistic shame-induced aggression. One explanation for this finding, based on self-verification theory, is that narcissistic youth with high self-esteem are more vulnerable to shameful events than are youth with low self-esteem. Another explanation is that narcissistic youth with high and low self-esteem do not differ in their vulnerability to shameful events, but they do differ in the way they deal with those events. This latter explanation is consistent with research showing that narcissists' interpersonal orientation tends to vary along with their level of self-esteem (e.g., Cain et al., 2007; Wink, 1991). *Overt narcissists*, who have high self-esteem, have been described as extraverts marked by a dominant and aggressive interpersonal orientation. *Covert narcissists*, who have much lower self-esteem (i.e., their self-absorption co-occurs with feelings of self-doubt and insufficiency), have been described as "worriers" marked by an anxious and internalizing interpersonal orientation. They may feel aggrieved and hurt when shamed, but in our experiment, they were not aggressive.

Researchers have argued that aggression is an appealing behavioral alternative to shamed individuals because it serves an ego-protective function (Tangney & Dearing, 2002). Aggression provides immediate relief from the pain of shame, which is a tempting benefit in the short run. In the long run, however, predispositions to behave aggressively when shamed may have serious costs. Children who persistently deflect the painful feelings associated with their flaws and shortcomings may become less motivated to overcome them. Consequently, they may become less well adapted to the demands of their social environment. Also, affectively aggressive children are unpopular with peers (e.g., Price & Dodge, 1989; Prinstein & Cillessen, 2003). Thus, aggressive behaviors meant to discard shame in the short run may ironically increase children's liability to be the target of victimization in the long run.

The present experiment contributes to the literature in several ways. To our knowledge, it is the first study to examine the link between youth's self-views and their actual aggressive behavior in an in vivo situational context. Other studies have relied on measures of reported aggression that often include more diffusely defined antisocial acts such as lying or stealing (e.g., Donnellan et al., 2005). Our findings are consistent with those of previous work that found that narcissism is linked to reported aggression and conduct problems in youth (C. T. Barry et al., 2003; T. D. Barry et al., 2007). Also, the present experiment highlights the importance of shame as an emotional context for examining the link between self-views and aggression. Most important, this experiment shows the value of differentiating among different forms of self-view (Salmivalli, 2001). Most previous research involving children has relied exclusively on measures of self-esteem, which by itself is an unreliable predictor of aggression. This study indicates that narcissism is an important predictor of aggression, especially in the context of shame.

Limitations and Future Research

We have argued that early adolescence is an ideal age period for the present experiment. However, our developmental focus limits the ability to make generalizations to other age periods. Future research should test whether the link between self-views and aggression is moderated by age. Such knowledge would help clinicians to identify critical age periods to target the self-views underlying children's aggressive behavior.

The parental consent rate for our experiment was low (i.e., 29%). This may have occurred because the letter from the principal endorsing our study was accidentally not included with the consent form. Low parental consent does not threaten the internal validity of our experiment because participants were randomly assigned to shame or no-shame groups. We cannot, however, exclude the possibility that self-selected biased sampling has influenced the magnitude of the experimental effects observed. Future research may assess the extent to which our experimental findings generalize to other community and noncommunity samples.

Experimental aggression research is sometimes criticized for using laboratory paradigms that are supposedly unrepresentative of "real-world" aggression. The validity of laboratory aggression paradigms (including the noise blast procedure we used) has been supported in two meta-analyses. One meta-analysis demonstrated high levels of convergence across a wide range of laboratory aggression measures (Carlson, Marcus-Newhall, & Miller, 1989). The other meta-analysis showed that "real" and laboratory measures of aggression are influenced in similar ways by situational variables (e.g., provocation) and by individual difference variables (e.g., trait aggressiveness; Anderson & Bushman, 1997).

In contrast to the adult literature, aggression in the context of self-esteem threats such as shame is rarely examined in the child literature. We believe this is unfortunate because such threats are common experiences (particularly in early adolescence) known to elicit aggression in subsets of children (Dodge, Coie, & Lynam, 2006). In this experiment, we manipulated a situation of self-attributable shortcoming. However, shame and other self-esteem threats can also result from shortcomings pinpointed by others. In fact, peer harassment among schoolchildren typically involves damaging others' self-esteem or status (Galen & Underwood, 1997; Nishina & Juvonen, 2005). Continued research on shame-induced aggression is needed to obtain a more complete view on the emotional processes involved in children's and adolescents' aggression.

Conclusion

Many efforts to reduce violence and aggression in youth have relied on boosting self-esteem (e.g., Kusché & Greenberg, 1994; Ringwalt, Graham, Paschall, Flewelling, & Browne, 1996). Although intuitively plausible, there are no clear theoretical or empirical reasons why boosting self-esteem should be effective in reducing aggression. In fact, the present experiment suggests that practices aimed at boosting self-esteem may even bring substantial costs. If these practices cultivate the inflated views of self that are characteristic of narcissism, they are likely to increase (rather than to decrease) the aggressive behavior of youth at risk.

Promoting Academic and Social-Emotional School Readiness: The Head Start REDI Program

Karen L. Bierman, Celene E. Domitrovich, Robert L. Nix, Scott D. Gest, Janet A. Welsh,
Mark T. Greenberg, Clancy Blair, Keith E. Nelson, and Sukhdeep Gill
The Pennsylvania State University

Forty-four Head Start classrooms were randomly assigned to enriched intervention (Head Start REDI—*Re*search-based, *D*evelopmentally *I*nformed) or "usual practice" conditions. The intervention involved brief lessons, "hands-on" extension activities, and specific teaching strategies linked empirically with the promotion of: (a) social-emotional competencies and (b) language development and emergent literacy skills. Take-home materials were provided to parents to enhance skill development at home. Multimethod assessments of three hundred and fifty-six 4-year-old children tracked their progress over the course of the 1-year program. Results revealed significant differences favoring children in the enriched intervention classrooms on measures of vocabulary, emergent literacy, emotional understanding, social problem solving, social behavior, and learning engagement. Implications are discussed for developmental models of school readiness and for early educational programs and policies.

Head Start has been referred to as the nation's "premier" federally sponsored early childhood education program developed to reduce socioeconomic disparities in school readiness (U.S. Department of Health and Human Services [USDHHS], 2005). In general, research suggests that comprehensive, high-quality preschool programs can improve the school readiness of disadvantaged children and have extended benefits over time (Barnett, 1995; Ramey & Ramey, 2004). The recent Head Start Impact Study, which compared children randomly assigned to receive Head Start with a similar group allowed to enroll in community non–Head Start services, demonstrated significant benefits. For example, for children attending 1 year of Head Start, statistically significant effects were found on four (of six) cognitive skills measured (with effect sizes ranging from .13 to .34) and on one (of three) social-emotional indices of school readiness (USDHHS, 2005). However, no effects were found on several important aspects of school readiness, including oral comprehension skills, phonological awareness, aggressive behaviors, or social skills. Although Head Start programs provide a strong infrastructure for service delivery, these findings demonstrate a need to further strengthen their educational programs to enhance the impact on child school readiness.

Developed in partnership with Head Start programs, the Head Start REDI (*Re*search-based, *D*evelopmentally *I*nformed) intervention targets the promotion of specific school readiness competencies in the domain of social-emotional development (prosocial behavior, emotional understanding, self-regulation, and aggression control) and cognitive development (language and emergent literacy skills). This article reports on the 1-year child outcomes of REDI assessed using a randomized-controlled design, with multi-informant, multimethod measurement.

Head Start Programs: High/Scope and Creative Curriculum for Preschool

The majority of Head Start programs in the nation use either the High/Scope curriculum, first developed in 1962 (Weikart & Schweinhart, 2005) or the Creative Curriculum for Preschool, first developed in 1978 (Dodge, Colker, & Heroman, 2002). Both of these core curricula emphasize the importance of child-initiated learning supported by positive teacher–child relationships and strategic learning interactions. Brief teacher presentations introduce a mix of large- and small-group exploratory activities each day. In High/Scope, teachers then use a formal "plan, do,

---

This project was supported as part of the Interagency School Readiness Consortium by National Institute of Child Health and Human Development Grants HD046064 and HD43763. We express deep gratitude to Gloria Rhule, Harriet Darling, and Julia Gest for the extensive contributions they made to intervention development and implementation. In addition, appreciation is expressed to the teachers, students, parents, and program personnel who served as partners in this project in the Huntingdon, Blair, and York County Head Start programs of Pennsylvania.

review" process to guide children in anticipatory planning, inquiry-guided exploration, and experimentation. Both programs encourage individualized scaffolding (such as "mutual thinking") to elicit student interest and target individualized educational objectives in the context of student activity. Teachers also use large group activities (e.g., games, songs, musical activities) to foster a sense of community and provide practice in social skills and group problem solving. A randomized trial evaluating the High/Scope Perry Preschool Curriculum has demonstrated the inherent potential of this approach, revealing long-term benefits, including higher rates of high school graduation, fewer crimes, and better employment outcomes among children who participated in the Perry Preschool program compared to those who attended no preschool (Schweinhart et al., 2005). Unfortunately, "typical" Head Start programs have not produced the same effects. This is likely due to weaknesses in the fidelity of curriculum implementation and a failure to include the level of parent-focused home visits, teacher training, and organizational support that were used in the High/Scope trial and are recommended by the program developers (Schweinhart, 2004).

Although based on the best research-based developmental practices of the time, both High/Scope and Creative Curriculum originated before contemporary research identified certain predictors of preschool language and emergent literacy skills and before strategies for facilitating social-emotional competencies were empirically evaluated in preschool settings. Both models have incorporated new emphases on literacy and social skills into their programs based on more recent research; however, achieving high-fidelity implementation in the field remains a challenge. Part of the challenge may be that both programs rely on teacher expertise to individualize educational plans. Yet, many Head Start teachers feel overstressed and poorly equipped to handle behaviorally challenging and language delayed children who are often disengaged in the preschool learning context (Yoshikawa & Knitzer, 1997). In addition, Head Start staff often lack the research expertise, financial resources, and technical assistance necessary to integrate new research-based strategies effectively and with high-implementation fidelity, into their local programs (Iutcovich, Fiene, Johnson, Koppel, & Langan, 1997).

Head Start REDI was designed to make the integration of research-based practices easier by providing teachers with manualized enrichment curricula, consisting of brief lessons, "hands-on" extension activities, and specific instructional strategies, all arranged strategically to address a scope and sequence of social-emotional and language/emergent literacy skills. In addition, mentoring was provided to support teacher understanding and effective use of these instructional strategies. The REDI program was designed to enrich and complement the broad educational programming provided by High/Scope or Creative Curriculum, increasing the systematic emphasis teachers placed on target skills. These skills were selected because they are important predictors of grade school adjustment and achievement and are associated with socioeconomic disparities in school readiness (Blair, 2002; Ladd & Profilet, 1996). In addition, in all cases and as described in the following sections, prior efficacy studies had demonstrated instructional approaches that produced improvements in the skills, and these instructional approaches provided a basis for the REDI program design.

Social-Emotional Skills

At school entry, children are faced with heightened demands for well-regulated and goal-directed activity, including sustained behavioral inhibition, compliance with rules, and the capacity to initiate and sustain positive interpersonal relationships with teachers and peers (Campbell & von Stauffenberg, 2008; Kellam, Rebok, Ialongo, & Mayer, 1994). Children growing up in poverty are particularly likely to enter school with significant deficits in social-emotional readiness, with over 40% demonstrating delays in social competencies and communication abilities at school entry and over 20% exhibiting high rates of disruptive behavior problems that undermine school adjustment (Kaiser et al., 2000). To a considerable extent, these child skill deficits reflect the negative impact of poverty—and factors associated with it, such as maternal depression and exposure to violence and stress—on parenting practices (Lengua, Honorado, & Bush, 2007; Li-Grining, 2007).

Target skills. Specific social competencies linked empirically with school success include prosocial behaviors that foster positive peer and teacher relationships (e.g., helping, sharing, taking turns) and self-regulation skills that support the inhibitory control of aggression (Coolahan, Fantuzzo, Mendez, & McDermott, 2000; Denham & Burton, 2003; Ladd, Buhs, & Seid, 2000). Effective prosocial engagement and self-regulation, in turn, appear closely linked with emotional competence (e.g., the ability to recognize and regulate emotions; Denham & Burton, 2003) and with social problem-solving skills (e.g., the capacity to define problems, generate and consider alternative solutions, and engage in anticipatory planning that considers the consequences of various solutions; Crick & Dodge, 1994; Youngstrom et al., 2000).

In addition to these social behaviors, the social-emotional and self-regulation competencies that support effective learning engagement are important for school success (Blair, 2002). These include the capacity to participate cooperatively in classroom activities and to control attention and sustain task involvement (Ladd et al., 2000; McClelland, Acock, & Morrison, 2006). Children who can organize their behavior in a manner consistent with classroom expectations and engage with persistence on learning tasks exhibit higher levels of achievement in school (McClelland et al., 2006). Conversely, attention problems undermine effective learning and contribute to off-task behavior and reduced achievement (Hughes & Kwok, 2006). Although biological factors contribute to individual differences in children's attention skills and effortful control, socialization and educational experiences also appear to play an important role (Blair, 2006). As a result, interventions that foster social-emotional learning and improve behavioral self-regulation can strengthen cognitive development (Riggs, Greenberg, Kusche, & Pentz, 2006).

Intervention approaches. A rapidly growing research base suggests that social-emotional competencies (in areas of prosocial behaviors, aggression control, emotional understanding, social problem-solving skills, and learning engagement) can be enhanced via the use of systematic instructional approaches in the classroom (Consortium on the School-Based Promotion of Social Competence, 1994; Elias et al., 1997). Preschool teachers exert strong socialization influences on young children, affecting social-emotional learning in both formal and informal ways (Denham & Burton, 2003; Pianta & Stuhlman, 2004). Training teachers to provide warm support and effective (nonpunitive) classroom management has positive effects on children's prosocial behavior and reduced aggression (Webster-Stratton, Reid, & Hammond, 2004). In addition, explicit social-emotional learning and emotion coaching curricula enhance child skill development. For example, in a pioneering study, the "I Can Problem Solve" program promoted gains in children's social problem-solving abilities and teacher-rated improvements in frustration tolerance, impulsivity, and task engagement (Shure & Spivack, 1982). Similarly, a randomized trial of the "Al's Pals: Kids Making Healthy Choices" program produced significant effects on Head Start teacher ratings of child behavior problems and independent functioning (Lynch, Geller, & Schmidt, 2004). Further, children with behavior problems who received the "Dinosaur School" program (targeting prosocial skills, emotional understanding, self-regulation, and social problem-solving skills) showed behavioral improvements at home and school that were maintained at follow-up 1 year after the end of the program (Webster-Stratton et al., 2004).

Of particular importance to the current study, a comprehensive, universal social-emotional learning program, Preschool PATHS (Promoting Alternative Thinking Strategies; Domitrovich, Cortes, & Greenberg, 2007) demonstrated positive effects when delivered by teachers in Head Start classrooms. In a randomized trial, Head Start children who received Preschool PATHS showed higher levels of emotional understanding and were rated more socially competent by teachers and parents than children in the control group (Domitrovich et al., 2007).

Language and Emergent Literacy Skills

Language skills support social-emotional adjustment and foster childrens' abilities to understand and comply with the behavioral demands of school (Catts, Fey, Zhang, & Tomblin, 1999). In addition, oral language skills, along with phonological awareness and print knowledge, provide an important foundation for success in the early years of formal reading instruction (Catts et al., 1999; National Research Council, 1998; Stanovich & Siegel, 1994). Children who start school with deficits in these language and emergent literacy skills are frequently identified as poor readers in elementary school and rarely catch up to their nonimpaired peers, often suffering life-long reading disabilities and underachievement (Shaywitz & Shaywitz, 2005).

Target skills. Oral language skills include vocabulary, and the child's ability to understand and produce grammatically varied utterances and narratives. Oral language skills are critical to the process of extracting meaning both from printed text and from teachers' oral instruction. Exposure to a responsive and expansive language environment, in the context of warm, positive relationships with parents and teachers sets the stage for positive language learning (Dickinson & Smith, 1994). Children growing up in families of lower socioeconomic status are less likely than their economically advantaged peers to experience extended discussions with their caregivers or to engage in interactive reading (Senechal & LeFevre, 2002) and hence have less exposure to decontextualized and rich talk that expands vocabulary, fosters narrative skills, and allows them to reflect on their learning experiences.

Phonological awareness, which develops during the preschool years, refers to the ability to recognize and manipulate the smaller units of sound within spoken words, such as syllables and phonemes (Lonigan, Burgess, & Anthony, 2000). Preschoolers who are able to rhyme, blend sounds together to form new sounds, and segment sound into words or syllables are more proficient readers in first and second grades, even when IQ and vocabulary skills are controlled (Bryant, MacLean, Bradley, & Crossland, 1990; Catts et al., 1999). Conversely, children with reading disabilities often exhibit deficits in phonological awareness (Torgesen, 1998). Print knowledge, particularly the child's ability to identify letters of the alphabet, also plays a central role in the child's emerging ability to decode printed text (Scarborough, 2001).

Intervention strategies. Interactive book reading, when combined with professional development activities designed to improve the quality of teacher's language use has proven effective in promoting richer conversational exchanges in the classroom and gains in child vocabulary and oral comprehension skills (Wasik & Bond, 2001; Whitehurst, Arnold, et al., 1994; Whitehurst, Epstein, et al., 1994). In addition, there is compelling evidence that carefully sequenced learning activities can substantially enhance preschool children's phonological awareness and thereby contribute to early reading success (Adams, Foorman, Lundberg, & Beeler, 1998; Hatcher, Hulme, & Ellis, 1994) with some evidence of lasting effects through the end of elementary school (Byrne, Fielding-Barnsley, & Ashley, 2000). In addition, prior efficacy studies have also demonstrated that adding explicit preschool instruction in alphabetic principles fosters later word decoding (Lonigan et al., 2000) and can be combined effectively with phonological awareness interventions to produce gains in reading achievement (Ball & Blachman, 1991; Bradley & Bryant, 1983).

The Present Study

The Head Start REDI program was designed as an enrichment intervention that could be integrated into the existing framework of Head Start programs using the High/Scope or Creative Curriculum. REDI was organized to promote teachers' capacities to use research-based practices in supporting the development of both social-emotional competencies and language/emergent literacy skills. Empirically supported interventions were used or adapted for use in this context, and teachers received training workshops and ongoing weekly mentoring to support their use of the curriculum and teaching strategies. To examine its effects, the REDI Project employed a randomized trial design, assigning 44 classrooms to intervention or "usual practice" conditions. A large, ethnically diverse group of 4-year-old children were pretested as they entered these Head Start classrooms and were assessed again at the end of the year.

It was hypothesized that the REDI intervention would accelerate skill acquisition in the targeted domains of language development (vocabulary, syntax), emergent literacy (phonological awareness, print knowledge), and social-emotional skills (emotional understanding, social problem solving). It was further hypothesized that children would improve in socially competent behavior and learning engagement (increased classroom participation, fewer attention problems) and show reduced aggression, particularly at school, and possibly generalized to home.

Method

Participants

Participants in this study included two cohorts of 4-year-old children (N = 356, 17% Hispanic, 25% African American, and 54% girls) in 44 Head Start classrooms in three counties in Pennsylvania. Half of the participating classrooms came from a large, fairly densely populated county in the southeastern part of the state, which included an urban community surrounded by smaller communities. The other classrooms came from two smaller counties in the central part of the state, characterized by small towns and rural areas. Initially, classrooms were stratified on location, length of program, and student demographics to assure even representation in the intervention and comparison conditions. In the more urban county, classrooms were stratified into three groups, which varied in terms of urban (vs. nonurban) location, percentage of minority students served, and use of Spanish in the classroom. In the two more rural counties, classes were also stratified into three groups, which varied in terms of being full-day or half-day programs and located in small towns versus rural locations. Classrooms in the same center were always assigned to the same condition, to avoid inadvertent contamination of condition within centers. Within each stratified group, centers were randomly assigned to intervention or comparison conditions. This process resulted in 14 classrooms (67%) in each condition that were located in small centers (1–2 classrooms) and 8 classrooms in each condition located in four larger centers (containing 3–5 classrooms), with children from ethnic minority groups fairly evenly spread across condition (39% of the intervention group and 45% of the control group.)

Children were recruited across 2 years. Each year, teachers were studied as they implemented the intervention for the first time, and 4-year-old children were assessed after receiving 1 year of REDI intervention. Teachers in the comparison classrooms continued to conduct curriculum "as usual." On average, classrooms contained about 14 children (typically, one-third 3-year-olds, two-thirds 4-year-olds). Approximately 60% of the 4-year-olds recruited for this study had attended Head Start as 3-year-olds, and this proportion was similar across the intervention and control classrooms. Pretest scores for all children were used to control statistically for initial differences in child skills.

To recruit participants for the evaluation trial, brochures describing the study were distributed to parents of all 4-year-old children in participating classrooms. Overall, only 14 eligible families declined to participate in the evaluation procedures, but an additional 21 primary caregivers were very difficult to reach and failed to complete the preassessment. Two children were dropped because they had a twin or sibling in the study, and 19 families withdrew early from Head Start and hence completed only parts of the assessment procedures. Hence, study participants represent 86% of the initially eligible population. Primary caregivers included 89% mothers, 4% fathers, 4% grandparents, and 3% other, including stepparents or foster parents.

Data Collection Procedures

Parent interviews were conducted at a time and location that was convenient for the parents (e.g., at the Head Start center, their home, or at a community location such as a library). A trained interviewer met privately with the primary caregiver and read through all the measures. Based on teacher recommendation or parent request, some interviews were conducted in Spanish. Parent interviews were initiated shortly before the start of the school year and continued through the end of October. Parents were reinterviewed at the end of the school year, in May and June. Each time, parents were compensated $20 for this 30-min interview.

Child assessments were conducted at school by trained interviewers, during two individual 30- to 45-min "pull-out" sessions. After each session, interviewers rated the child's task-approach and learning behaviors, as observed during the session. To give children time to acclimate to the classroom setting, assessments began 3 weeks after school began and continued through the end of October. End-of-year child assessments were conducted in March and April.

End-of-year child ratings were collected from teachers in April. Teachers were compensated $20 to provide general information about themselves and their classrooms, and they received an additional $7 per child for completing behavioral ratings. One lead and one assistant teacher in each classroom provided independent ratings of child behavior.

Beginning in April, each child was observed during two 12- to 15-min play sessions held on 2 separate days. Using a roster generated by the research staff, classmates were randomly assigned to groups of three, taken to a separate space, and given the opportunity to play with an interesting and novel toy together (playground set and castle set). By using a standard play setting that encouraged social interaction, these sessions were designed to control for classroom variations in play opportunities and to elicit meaningful individual differences in social competencies. Observers were naive concerning the intervention or control status of the children. One observer focused on each child, noting discrete social behaviors and interactions, and at the end of the session, completed rating forms describing the quality of social behavior observed.

Intervention Design

The intervention was delivered by classroom teachers and integrated into their ongoing classroom programs. It included curriculum-based lessons, center-based extension activities, and training in "teaching strategies" to use throughout the day.

Social-emotional skill enrichment. The Preschool PATHS Curriculum (Domitrovich, Greenberg, Cortes, & Kusche, 1999) was used to promote children's social-emotional skills. This curriculum targets four domains: (a) prosocial friendship skills, (b) emotional understanding and emotional expression skills, (c) self-control (e.g., the capacity to inhibit impulsive behavior and organize goal-directed activity), and (d) problem-solving skills, including interpersonal negotiation and conflict resolution skills. The curriculum is divided into 33 lessons that are delivered by teachers during circle time. These lessons include modeling stories and discussions and use puppet characters, photographs, and teacher role-play demonstrations. Each lesson includes extension activities (e.g., cooperative projects and games) that provide children with opportunities to practice the target skills with teacher support. Teachers taught one PATHS lesson and conducted one extension activity each week.

Generalized teaching strategies were encouraged with mentoring, including positive classroom management, use of specific teacher praise and support, emotion coaching, and induction strategies to promote appropriate self-control.

Language/emergent literacy skill enrichment. Four language and emergent literacy skills were targeted in REDI: (a) vocabulary, (b) syntax, (c) phonological awareness, and (d) print awareness. Three program components were developed to target these skills, including an interactive reading program, a set of "Sound Games," and print center activities.

The interactive reading program was based on the shared reading program developed by Wasik and Bond (2001; Wasik, Bond, & Hindman, 2006), which was, in turn, an adaptation of the dialogic reading program (Whitehurst, Arnold, et al., 1994). The curriculum included two books per week, which were scripted with interactive questions. Each book had a list of targeted vocabulary words, presented with the aid of physical props and illustrations. In addition to presenting these materials in a systematic way during the week, teachers received mentoring in the use of "language coaching" strategies, such as expansions and grammatical recasts, to provide a general scaffold for language development in the classroom (Dickinson & Smith, 1994). The overall goal was to improve teacher's strategic use of language in ways that would increase child oral language skills, including vocabulary, narrative, and syntax.

Teachers were provided with curricula materials to promote phonological awareness and print knowledge. A set of Sound Games was based primarily on the work of Lundberg and colleagues (Adams et al., 1998). The games were organized developmentally, moving from easier to more difficult skills during the course of the year (e.g., listening, rhyming, alliteration, words and sentences, syllables, phonemes.) Teachers were asked to use a 10- to 15-min Sound Game activity at least three times per week.

In addition, teachers were provided with a developmentally sequenced set of activities and materials to be used in their alphabet centers, including letter stickers, a letter bucket, materials to create a Letter Wall, and craft materials for various letter-learning activities. They were asked to make sure that each child visited the alphabet center several times per week and were given materials to track the children's acquisition of letter names.

Training and professional development support. Teachers received detailed manuals and kits containing all materials needed to implement the intervention. A 3-day professional training was conducted in August, prior to initiating the intervention, and a 1-day "booster" training session was conducted in January. Teachers also received weekly mentoring support provided by local educational consultants ("REDI trainers"), experienced master teachers who were supervised by two project-based senior educational trainers. The weekly consultations were intended to enhance the quality of implementation through modeling, coaching, and providing ongoing feedback regarding program delivery. REDI trainers spent an average of 3 hr per week ($SD = 0.18$) in each classroom observing, demonstrating, or team teaching lessons. They also met with the head and assistant teacher for 1 hr each week outside of class.

Parent take-home materials. Three "take-home" packets were mailed to parents during the course of the year, each containing a modeling videotape, with parenting tips and learning activities to use at home. In addition, the PATHS curriculum included handouts for parents, with suggestions for home activities. Children also took home letter stickers and compliment pages to prompt their parents to ask them about their school day and provide positive support at home.

Integrating the program components. Half of the participating classrooms used High/Scope as their base curriculum; the others used Creative Curriculum. Project staff developed "crosswalk" tables to illustrate how the REDI target skills and methods mapped onto each of these base curricula. Although both High/Scope and Creative Curriculum have recently developed supplemental materials to enhance language and emergent literacy skills, none of the Head Start programs participating in this project were using them. The interactive reading program and emphasis on language use, as well as the emotion coaching and social problem-solving strategies that were central to the REDI program were philosophically compatible with the strategic, child-centered teaching approach used in High/Scope and Creative Curriculum. They were easily integrated into existing book reading, learning center, and play activities and routines. The Sound Games, alphabet centers, and social-emotional lesson presentations used more direct teacher instruction, and hence represented components that were not well integrated with the core curriculum but were "added on" to enhance the acquisition of specific skill concepts.

A central objective of REDI was to maximize the integration of the social-emotional and language/emergent literacy intervention components that comprised the enrichment program. Each week, one of the books used in the interactive reading program focused on the PATHS theme for that week (e.g., friendship, feelings, self-control, social problem solving), and feeling words were included in the vocabulary prompts. Conversely, PATHS extension activities incorporated language and emergent literacy skills.

Intervention implementation. Teachers reported to REDI trainers regarding the enrichment lessons and activities they used. On average, each week they reported implementing 1.77 PATHS lessons and extension activities (*SD* = 0.12), 6.08 dialogic reading activities (*SD* = 0.25), 2.57 sound game activities (*SD* = 0.34), and 3.56 alphabet center activities (*SD* = 0.18). In addition, teachers answered 10 questions, using 3-point scales to describe the quality of their implementation (e.g., Were you able to complete the lesson as written? How well did the children understand the major points of the lesson?; α = .87). The average rating was 2.78 (*SD* = 0.15) indicating that, from the teachers' perspective, the curriculum was being delivered with high fidelity, and children were engaged in the lessons.

On a monthly basis, REDI trainers assessed the fidelity and quality of implementation of program components, using a 6-point Likert scale (*poor* to *exemplary*). Implementation quality ratings were: PATHS, *M* = 4.61 (*SD* = 0.74), dialogic reading, *M*=4.39 (*SD* = 0.57), alphabet activities, *M* = 4.70 (*SD* = 0.55), sound games, *M*=4.52 (*SD* = 0.72), and overall REDI program, *M* = 4.55 (*SD* = 0.67). Scores of 4–5 reflected descriptions of "adequate" to "strong."

Measures

A multimethod, multimeasure assessment battery included child assessments, teacher ratings, parent ratings, and direct observations. Outcome measures represented six core domains: (a) language skills, (b) emergent literacy skills, (c) emotional understanding and social-cognitive skills, (d) social behaviors, (e) learning engagement at school, and (f) learning engagement at home.

Language skills. Three tests were administered directly to children to assess their language skills. In the Expressive One-Word Picture Vocabulary Test (Brownell, 2000), children gave the word that best described pictures they were shown (α = .94.) The Grammatical Understanding subtest of the Test of Language Development (TOLD; Newcomer & Hammill, 1997) assessed syntax comprehension. Children listened to a sentence and chose one of the four pictures that "best matched" the meaning of the sentence (α = .80). The Sentence Imitation subtest assessed syntax expression. Children repeated sentences read aloud by the interviewer. Scores reflected the number of increasingly complex sentences a child imitated correctly (α = .90). Prior research has documented strong test–retest reliability for TOLD subtests (*r* = .90) and concurrent validity with comprehensive language assessments (Newcomer & Hammill, 1997).

Emergent literacy skills. Three subscales assessing emergent literacy skills were drawn from the Test of Preschool Early Literacy (TOPEL; previously labeled the Pre-CTOPP; Lonigan, Wagner, Torgesen, & Rashotte, 2007). The Blending subtest assessed phonological processing. Children were asked to combine different parts of a word, such as "hot" and "dog" or "b" and "air" and point to the correct picture or say the full word (α = .86). On the Elision subtest of the TOPEL, children deconstructed compound words and pointed to the correct picture (e.g., Point to "snowshoe" without "snow"; Say "airport" without "air"; α = .83). In the Print Knowledge subtest of the TOPEL, children identified pictures of letters or words and named letters (α = .97). Prior research has reported correlations in the range of .43–.88 between these three subscales and the acquisition of initial reading skills (Lonigan, 2006).

Emotional understanding and social-cognitive skills. Two measures assessed emotional understanding. On the Assessment of Children's Emotion Skills (Schultz, Izard, & Bear, 2004), children determined whether the facial expressions in 12 photographs reflected happy, mad, sad, scared, or no feelings. The score was the total number correctly identified (α = .57). On the Emotion Recognition Questionnaire (Ribordy, Camras, Stafani, & Spacarelli, 1988), children listened to 16 stories describing characters in emotionally evocative situations and identified their feeling by pointing to pictures of happy, mad, sad, or scared faces. Children received a score of 2 for correctly identifying the feeling and a score of 1 for correctly identifying the valence (α = .63).

Social problem-solving skills were assessed using a variation of the Challenging Situations Task (Denham, Bouril, & Belouad, 1994.) Children were presented with pictures of four peer scenarios (e.g., a peer knocking down blocks, being hit, entering a group, a peer taking a ball). After each scenario, children were asked what they would do in the situation. Their open-ended responses were coded as competent (i.e., appropriately asserting oneself or calmly negotiating a solution, α = .68), aggressive (i.e., responding with verbal or physical antagonism, intimidation, or force, α = .77), or inept (i.e., passive avoidance, α = .68). Coding agreement between research assistants and data checkers on 1,616 responses was high (κ = .94).

Social-emotional behaviors. Teacher ratings, observer ratings, and parent ratings assessed social competence and aggressive-oppositional behavior. The 13 items of the Social Competence Scale (Conduct Problems Prevention Research Group [CPPRG], 1995) were rated on a 6-point Likert scale (*never* to *almost always*) and included prosocial behaviors such as sharing, helping, understanding other's feelings, as well as self-regulatory behaviors, such as resolving peer problems independently. Ratings provided by lead and assistant teachers were averaged (r = .56, p < .001). Internal consistency was high for teachers (α = .94) and parents (α = .87). Observers used the same rating scale to describe child behavior after each of the play observation sessions (α = .88). Interrater reliability was assessed for 23% of the playgroup sessions and demonstrated adequate agreement (intraclass correlation coefficient [ICC] = .70). Ratings collected after each of the two playgroup sessions were averaged (r = .24, p < .001).

Seven items from the Teacher Observation of Child Adaptation – Revised (TOCA – R; Werthamer-Larsson, Kellam, & Wheeler, 1991) assessed overt aggression (e.g., stubborn, yells, fights). Six items from the Preschool Social Behavior Scale – Teacher Form (Crick, Casas, & Mosher, 1997) assessed relational aggression (e.g., "Tells other kids he/she won't be their friend unless they do what he/she wants"). Items were rated on a 6-point Likert scale (*almost never* to *almost always*; α = .88 and .93, for the two scales, respectively). Ratings from lead and assistant teachers were averaged (r = .68, p < .001, for overt aggression, and r = .51, p < .001, for relational aggression), and overt and relational ratings were combined to form a total aggression score (r = .58, p < .001). Parents and observers completed the seven items from the TOCA – R only (α = .86, α = .92, respectively). Interrater agreement among observers was acceptable (ICC = .74), and ratings were averaged across the two sessions (r = .42, p < .001).

Learning engagement at school. Teacher ratings were used to assess learning engagement at school, using an eight-item inventory developed for this study. Items were rated on a 6-point Likert scale (*strongly disagree* to *strongly agree*), and reflected self-regulation (e.g., "Has the self-control to do well in school" and "Can follow the rules and routines that are part of the school day"), learning motivation and involvement (e.g., "Seems enthusiastic about learning new things"), and compliance (e.g., "Is able and willing to follow teacher directions"). Lead and assistant teacher ratings were averaged (α = .95, r = .70, p < .001).

Observers completed the Adapted Leiter – R Assessor Report (Roid & Miller, 1997) to assess task orientation at school (Smith-Donald, Raver, Hayes, & Richardson, 2007). After the child assessments, interviewers rated the child's participation and involvement, using 13 items (e.g., "Shows pleasure in accomplishment and active mastery," "Careful and interested in accuracy," "Alert and interactive.") Each item was rated on a 4-point scale (α = .93). Scores from the two assessment sessions were averaged (r = .62, p < .001).

Teachers also completed the ADHD Rating Scale (DuPaul, 1991). Based on the *Diagnostic and Statistical Manual* symptoms of attention deficit hyperactivity disorder, this scale includes 14 items reflecting attention problems (e.g., "Is easily distracted," "Has trouble following directions") each rated on a 4-point scale. Lead and assistant teacher ratings were averaged (α = .94; r = .76, p < .001) and used in this study to represent a continuous dimension reflecting difficulties with impulse control, distractibility, and sustained attention.

Learning engagement at home. Parents completed the ADHD Rating Scale (α = .90). In addition, they responded to five questions about children's language and communication at home (e.g., "How many times in a typical week do you and your child have a conversation that lasts 10 min or more?" "How often does your child volunteer to tell you about something that happened when you were not with him or her?"; α = .49). Finally, parents answered six questions about children's engagement in reading at home (e.g., "When was the last time you and your child read a book together?" "How many books did you read at that time?"; α = .63).

Results

Preliminary Analyses

Scores on Sentence Imitation and observer ratings of aggressive-oppositional behavior were highly skewed. Log transformations were conducted on those scores, after which all measures were normally distributed with values of skewness and kurtosis below 2.00. Correlations among the measures of child skills (language, emergent literacy, and social-emotional cognitions) are presented in Table 1, and correlations among the measures of child behavior ratings (by teachers, parents, and observers) are presented in Table 2.

To examine preintervention differences between the intervention and the comparison groups, hierarchical linear models (HLM) were estimated, accounting for the nesting of children within classrooms. Child sex and race were included as Level 1 covariates

and center site (e.g., central or southeastern Pennsylvania), cohort, and intervention status were included as Level 2 covariates in each of these models. No significant ($p < .05$) pretreatment intervention-control group differences emerged on the 11 measures of child skills or the 6 measures of child behavior for which pretreatment scores were available. Overall, the stratified randomization process appeared effective in creating equivalent groups prior to the intervention.

Postintervention Group Differences

The first set of analyses examined the 11 measures of child language, emergent literacy, emotional understanding, and social problem-solving skills that were targeted directly by the intervention and were measured using direct assessments of child skill knowledge. Because the intervention was delivered at the classroom level, analyses accounted for the nonindependence of data at that level. Child sex and race were included as Level 1 covariates and site, cohort, and intervention status were included as Level 2 covariates. Preintervention scores were available for all these measures and also were included as Level 1 covariates.

The results of these HLM are summarized in Table 3. For ease of interpretation, all measures were standardized with a mean of 0 and a standard deviation of 1. By doing this, the coefficient for the intervention effect represents the difference in average expected scores between children in the intervention and control groups as a proportion of a standard deviation. This difference is similar to

CST competent responses	2.37 (2.05)	2.29 (2.05)	2.51 (2.16)	3.16 (2.55)	.35	.005
CST inept responses	2.52 (2.11)	2.56 (2.34)	2.51 (2.11)	1.94 (2.01)	−.28	.03

Note. Group means are presented with standard deviations in parentheses. Effect estimates represent approximate effect size. CST = Challenging Situations Task.

an effect size that controls for all other measures in the HLM. There were significant treatment effects ($p < .05$) for 7 of the 11 skills directly targeted by the intervention and marginally significant intervention effects ($p < .10$) for 2 other skills. Only 2 of the skills (grammatical understanding and sentence imitation) showed no evidence of intervention impact. The effect size for the 9 skills showing an intervention effect ranged from .15 to .39. This suggests that children who received the REDI enrichment gained about one fourth of a standard deviation more in these areas of target skill acquisition than children in the control group who received usual practice Head Start.

Next, HLM analyses were conducted to assess intervention effects on the 12 behavioral ratings provided by teachers, observers, and parents. Ideally, the cognitive and social-emotional skills acquired by children in the intervention group, along with the emotion coaching and inductive support provided by their teachers should produce generalized improvements in social competence, aggression control, and learning engagement. As before, the HLM nested children within classroom, included child sex and race as Level 1 covariates and included site, cohort, and intervention status as Level 2 covariates. In this case, however, we only had preintervention parent ratings and preintervention observer ratings of task orientation as Level 1 covariates. As shown in Table 4, 3 of the 12 behavioral ratings showed significant ($p < .05$) intervention effects—teacher ratings of aggression, observer ratings of task orientation, and parent ratings of communication/language use. Five additional measures showed nonsignificant trends ($p < .10$) favoring intervention—teacher ratings of social competence, observer ratings of social competence, and parent ratings of aggression, attention problems, and reading involvement. Only four measures (parent ratings of social competence, observer ratings of aggression, teacher ratings of learning engagement, and teacher ratings of attention problems) showed no evidence of intervention impact. On the dimensions that showed marginal or statistically significant intervention effects, the effect sizes ranged from .11 to .29. Hence, children who received the REDI enrichment showed behavioral improvements in these areas that averaged about one fifth of a standard deviation more than the behavioral maturation observed in control group children.

Discussion

The Head Start REDI intervention was designed to capitalize on the existing service delivery infrastructure and quality programming of the Head Start system. The goal was to improve program impact on child skill acquisition by increasing the teachers' use of research-based instructional materials and teaching strategies. To do so, REDI provided supplementary curricula and mentoring to assist teachers

Table 4
Intervention Effects on Child Behaviors

	Control group		Intervention group		Intervention effect	
Variable	Pre	Post	Pre	Post	Effect	*p* value
Social-emotional behaviors						
Social competence: Teacher	NA	3.98 (0.88)	NA	4.15 (0.82)	.24	.10

who were using High/Scope or Creative Curriculum to incorporate language more effectively throughout the day, provide both explicitly taught and more generalized support for child social-emotional development, and include explicit instruction in phonological sensitivity and letter identification skills.

Prior studies have shown that model preschool programs can have strong and long-lasting effects on the educational attainment and life adjustment of children growing up in socioeconomically disadvantaged situations. However, Head Start programs are often underresourced in comparison, and many lack the high levels of teacher training and organizational support that characterize the most successful models (Schweinhart, 2004). Both High/Scope and Creative Curriculum encourage teachers to promote child-centered learning, individualizing their approach to expand on individual student interests and strengths. In addition, teachers are expected to use professional development workshops to master new, research-based strategies for promoting emergent literacy and social-emotional competences and to incorporate these strategies into their classroom practice. These expectations can create "overload" for teachers, who often lack the time, technical assistance, financial resources, and organizational support needed for effective and high-fidelity implementation (Iutcovich et al., 1997; Yoshikawa & Knitzer, 1997).

Head Start REDI sought to support teachers and improve the fidelity of research-based instructional practice in Head Start classrooms, by providing teachers with a well-specified enrichment curriculum, along with a year of mentored professional development in the implementation of that curriculum and corresponding teaching practices. The curriculum included specific instructional strategies and hands-on extension activities that were strategically diffused within the context of regular High/Scope and Creative Curriculum activities, as well as "scripted" lessons, all carefully organized to address a scope and sequence of language/emergent literacy and social-emotional skills.

The Program Impact on Child School Readiness

Language skills and social-emotional competencies were targeted for emphasis in REDI because these skills provide fundamental support for effective school engagement; they facilitate the child's ability to follow classroom rules, cope actively with learning challenges, and relate to teachers and peers (McClelland et al., 2006). These skills are intertwined developmentally. Language skills enhance the child's capacity to regulate emotions and promote effective social interaction (Greenberg, Kusche, & Speltz, 1991), and conversely, social-emotional competencies foster positive adult and peer relationships, motivating and providing important opportunities for language learning and cognitive development (Bierman, Greenberg, & the Conduct Problems Prevention Research Group, 1996). A key feature of the REDI program was the synchronized and integrated focus on both language/emergent literacy skills and social-emotional competencies, designed to support skill development in both domains and foster transactional processes promoting cross-domain and comprehensive school readiness.

Teachers taught explicit lessons on social-emotional skills and, with mentoring, were encouraged to use emotion coaching, induction strategies, and problem-solving dialogue techniques throughout the day to encourage child social-emotional development. Statistically significant effects emerged on direct assessments of children's emotional understanding and social problem-solving skills, reflecting modest effect sizes (range = .21 – .35). Corresponding improvements were also noted on measures of behavioral functioning, although not as consistent or strong as the impact on the targeted social-cognitive skills. Specifically, statistically significant differences in aggression were reported by teachers and statistically significant improvements in task orientation were reported by observers. Nonsignificant trends also favored children in the intervention classrooms on measures of teacher- and observer-rated social competence and parent-rated aggression and attention problems. Effect sizes ranged from .11 to .29. These are relatively small effects and require follow-up assessment in elementary school to determine whether they promote generalized and sustained improvements in school adaptation over time.

Additional REDI program components focused on improving classroom support for child language development (Dickinson & Smith, 1994). The interactive reading program provided teachers with scripted books and targeted vocabulary. Mentors encouraged teachers to elicit children's language more effectively and respond to it more sensitively. Mentors also encouraged teachers to model decontextualized and rich talk and to use questions and summaries to foster child narrative skills (Wasik & Bond, 2001; Whitehurst, Arnold, et al., 1994). Significant effects favoring children in intervention classrooms emerged on child vocabulary and on parent reports of communication and language use at home (with effect sizes of .15 and .25, respectively), but no effects emerged on the measures of child grammatical understanding.

In addition, the REDI curriculum used explicit instruction to promote the discrete skills of phonological awareness and print knowledge (Lonigan et al., 2000; Scarborough, 2001). Two indices of phonological awareness (blending and elision) showed a significant intervention effect; print awareness showed a nonsignificant trend favoring intervention (effect sizes ranged from .16 to .39). These findings suggest that the intervention successfully promoted the discrete skills targeted in this domain. However, follow-up data are required to determine whether these discrete skills foster early reading skill acquisition, as they are hypothesized to do.

Several major components of the REDI program—specifically, sensitive-responsive language use, emotion coaching, and social problem-solving dialogue—were philosophically compatible with the strategic, child-centered teaching approach used in High/Scope and Creative Curriculum. However, the use of explicit instruction (PATHS lessons, sound games, print center focus on letter identification) was less consistent with this philosophy because of the emphasis on direct instruction. Proponents of "developmentally appropriate practice" in preschool settings have concerns about explicit instructional techniques of this kind that teach skills in a decontextualized fashion. The main concern is that an overemphasis on explicit instruction may reduce the learning engagement of young children and stifle curiosity and exploratory learning. Countering these concerns are proponents of explicit instruction who cite evidence that emergent literacy skills (such as letter identification and phonemic awareness) are strong predictors of later school achievement that are not likely to be acquired by children in Head Start unless explicit instruction techniques are employed (Lonigan et al., 2000). The results of the Head Start REDI program suggest that it is possible to integrate empirically validated strategies for promoting these critical emergent literacy skills in ways that are consistent with Head Start practices. With support and mentoring, Head Start teachers implemented the REDI curriculum components with a high level of fidelity and quality throughout the year. Interactive reading techniques were integrated into preexisting read-aloud sessions, alphabet center activities were integrated into preexisting print centers, and PATHS lessons were conducted during preexisting morning "circle times." Sound games were most often added during transition periods, and PATHS extension support (emotion coaching and social problem-solving support) was used during free play periods. The significant effects on child skill acquisition suggest that this hybrid approach of incorporating some explicit instruction in the context of a child-centered, comprehensive early childhood program may be beneficial. Follow-up assessments are needed to determine the sustainability of these gains as well as to determine whether the program had any costs for children, in terms of reduced motivation or decreased gains in other domains of development.

Strengths and Limitations of the Study

Several strengths of the study warrant mention. The randomized-controlled design and use of multiple informants enhance confidence in the validity of the findings. Although teachers knew which children were receiving intervention, child assessors, observers, and parents were naive concerning the intervention/control status of the children. Hence, most of the measures used in the study were unbiased. HLM were used to control for the nesting of children within classrooms and to adjust for the potential dependencies in intervention effects associated with the classroom implementation of the program.

An added feature of this study involved the use of usual practice Head Start classrooms for a control group. Many of the studies that have produced larger effect sizes for preschool interventions have relied on comparison children who received no or minimum preschool support. This study demonstrated the effects of the enrichment relative to Head Start classrooms using standard High/Scope or Creative Curriculum, increasing the confidence with which the findings can be attributed to the specific teacher mentoring and supplementary curriculum used, rather than to more general features associated with the Head Start preschool experience.

A limitation of the study that should be noted, however, is that no measures were collected to determine the fidelity with which these programs were implementing their basic High/Scope or Creative Curriculum. It is possible that, had an equal amount of professional development effort been exerted to improve and monitor the fidelity of these core curricula, the results would have been similar to the impact of adding new curricular components. We hypothesize that providing teachers with a well-specified curriculum and lesson plans that are ordered along a developmental sequence makes it easier for them to introduce concepts and learning activities in a systematic and strategic manner. However, similar to most models of early childhood education, the REDI program assumes that young children acquire new skills when they are actively interested and engaged in goal-oriented activity, and hence that effective teaching requires sensitive and flexible responding to child-initiated inquiries and responses. For this reason, the REDI program included both a well-specified curriculum and a heavy emphasis on professional development and mentoring for teachers. The consequence is that one cannot determine whether either one of these components (without the other) would have been sufficient to promote the same child outcomes. It is quite possible that changes in teaching practices (e.g., enriched language use, more positive behavioral support, improved instructional quality) were the key features that accounted for positive changes in child outcomes. The REDI curriculum and mentoring program are likely just one of the several approaches that improve child outcomes via improvements in teaching quality.

In addition, the parent component of the REDI intervention was minimal, consisting of take-home handouts, videos, and a few parent–child activities. Even so, parents reported significant differences in child communication and language use at home and nonsignificant trends favoring intervention on the child's reading involvement, aggression, and attention problems at home. To a large degree, the negative impact of family poverty on child school readiness is mediated by home learning opportunities, particularly the quality of parent–child interactions and associated provision of cognitive stimulation and emotional support (Campbell & von Stauffenberg, 2008; Duncan, Brooks-Gunn, & Klebanov, 1994; Eccles & Harold, 1996). Hence, it seems quite likely that greater attention to parenting might strengthen program impact.

A third limitation of the present study involves the timing of the assessments. Because we needed to give children some time to acclimate to the classroom setting, and then work around classroom schedules, it took us 8 weeks at the beginning of the year to conduct all the child preintervention assessments. Similarly, we had to start the child postintervention assessments 8 weeks before the end of the school year. On average, the impact on child skills was evaluated on the basis of approximately 25 weeks of exposure of the 35-week program year.

Fourth, because we needed to assess young children with limited attention on a wide range of cognitive and social-emotional domains, we had to rely on very brief assessments of discrete skills that are assumed to reflect broader domains of school readiness. We do not know, for example, how well some of our indicators of emergent literacy will predict future reading ability, and we do not know how well postintervention differences on teacher ratings or the relatively brief behavioral observations will predict later social skills.

Relatedly, although REDI appears to have had a positive effect on children's development, we cannot know how robust those changes are. Follow-up data are needed on these children as they enter kindergarten and proceed into first grade to determine whether the gains observed on these measures will predict longer range benefits in school achievement and behavioral adjustment.

Implications for Early Educational Policies and Programs and Future Directions

The present findings suggest that the impact of Head Start on children's cognitive and social-emotional school readiness can be improved by incorporating research-based instructional strategies and teaching practices into existing high-quality curricula, such as High/Scope and Creative Curriculum. They also suggest that usual practice strategies for teacher training in research-based practices are insufficient. That is, during the course of this trial, teachers in control classrooms participated in Head Start – sponsored professional development workshops but were not able to leverage this training into changes in classroom practice that supported the same rate of student skill acquisition as did REDI. The specific and scripted REDI curricula may provide critical scaffolds to enhance improved practice, assisting teachers by organizing skill presentation along a scope and sequence, reducing teacher preparation time, and providing teachers with a platform for skill coaching throughout the day. This type of intensive skill focus may be most effective when it is integrated into a comprehensive, child-centered educational program, such as High/Scope and Creative Curriculum, which provides broad support for the child's overall development and emphasizes emotionally supportive and responsive teaching.

More broadly, the present program validates the strategy of enriching current "best practices" curricula with emerging research-based curriculum materials and teaching strategies. Given the limited number of hours in the school day, teachers sometimes feel that they must choose between focusing on the cognitive skills or the social-emotional needs of socioeconomically disadvantaged students. These findings demonstrate that a dual-focus integrated intervention model can effectively and simultaneously promote gains in both domains.

Teacher–child relationships were examined as predictors of cortisol change in preschool children. Saliva for assays was collected from one hundred and ninety-one 4-year-olds (101 boys) in the mornings and afternoons on 2 days at child care, and before and after a series of challenging tasks and a teacher–child interaction session outside the classroom. Parents reported on children's temperament, teachers and children reported on teacher–child relationship quality, and observers rated group-level teacher insensitivity. Teacher-reported relationship conflict predicted cortisol increases during teacher–child interaction and teacher-reported overdependence predicted cortisol increases from morning to afternoon, even after controlling for individual teacher, child, and classroom characteristics. The findings extend earlier work by suggesting that cortisol change across the child-care day is influenced by teacher–child relationship characteristics.

A majority of preschool-aged children in the United States experience out-of-home care (Cappizzano, Adams, & Sonenstein, 2000). Researchers, policy makers, and parents have raised concerns about the potential negative effects of child care on children's health and development (National Institute of Child Health and Human Development [NICHD] Early Child Care Research Network, 2003). A series of studies suggests that many children in full-time out-of-home care experience atypical increases across the day in cortisol, the primary stress hormone in humans (Dettling, Gunnar, & Donzella, 1999; Tout, de Haan, Campbell, & Gunnar, 1998; Watamura, Donzella, Alwin, & Gunnar, 2003; Watamura, Sebanc, & Gunnar, 2002). Although the significance of this phenomenon is still being debated (Granger & Kivlighan, 2003), elevation of cortisol under some conditions has been linked to immune suppression (Boyce et al., 1995), problems with learning, memory (Blair, Granger, & Razza, 2005; Seeman & McEwen, 1996), negative emotionality, and problem behavior (Granger, Stansbury, & Henker, 1994; Smider et al., 2002).

An important research agenda is to identify the child and child-care characteristics that are associated with cortisol elevations. Individual differences in cortisol secretion reflect a confluence of forces including previous experience, child characteristics, contextual demands, and social relationships (Granger, Stansbury, et al., 1994; Stansbury & Gunnar, 1994). However, a consistent theme across studies is that relationships with caregivers are critical in helping young children regulate hypothalamic-pituitary-adrenal (HPA) activity (Gunnar, 1998; Gunnar & Donzella, 2002; Levine & Wiener, 1988). Secure attachment relationships appear to buffer infants' HPA reactivity to challenge (Gunnar, 1998; Nachmias, Gunnar, Mangelsdorf, Parritz, & Buss, 1996). Children in child care develop attachment-type relationships with their care providers (Howes, Galinsky, & Kontos, 1998), and these relationships may serve a similar protective function (Gunnar, 1998) for young children (Cole, Michel, & Teti, 1994). Positive teacher relationships may provide external coping resources and an environment of perceived safety, whereas problematic relationships may affect children's physiological functioning both by failing to buffer the potential

stress of the classroom and by causing anxiety for the child during teacher–child interactions.

The purpose of this study was to examine the role of teacher–child relationships in influencing cortisol levels in young children in child care. Cortisol changes were measured in two settings: (a) from morning to afternoon in the classroom and (b) outside the classroom across a series of challenging tasks and a teacher–child interaction. We expected that children with poorer quality relationships with teachers would show greater cortisol increases from morning to afternoon in the classroom and over the teacher–child interaction episode outside of the classroom. To assess cortisol changes across the day, saliva samples were collected from children enrolled in full-day community child care in the mornings and afternoons of 2 separate days. Because many factors operating in a child-care classroom may influence children's HPA axis functioning, we also collected saliva from children in an out-of-class activity consisting of two segments. The first segment involved a series of mildly challenging tasks selected to simulate events young children might face in the classroom setting. The second segment consisted of a nonchallenging interaction with the child's teacher. The teacher–child interaction session allowed for the isolation of teacher–child relationship effects from potential classroom influences. We also assessed potential child-, measurement-, and classroom-level influences on children's HPA activity. These included child age (Gunnar, Tout, de Haan, Pierce, & Stansbury, 1997), sex (Kirschbaum, Wust, & Hellhammer, 1992), temperament (Davis, Donzella, Krueger, & Gunnar, 1999; Gunnar, 1994), family socioeconomic status (SES; Lupien, King, Meaney, & McEwen, 2000, 2001), time of day (Tout et al., 1998), group size (Legendre, 2003), and teacher characteristics (Dettling, Parker, Lane, Sebanc, & Gunnar, 2000).

Method

Participants

Child participants were enrolled in a larger study examining associations between preschool experience and the transition to kindergarten. All recruitment and data collection procedures were approved by Auburn University's institutional review board. Twelve child-care centers in two adjacent small communities in the Southeastern United States participated. The centers served children from low-income families ($n = 2$), served employees of a regional hospital ($n = 1$), served employees of a public school system ($n = 1$), were operated by a church ($n = 1$), or were private/for profit ($n = 7$). Children in 4-year-old classrooms (i.e., children who would attend kindergarten the following year) were eligible to participate. Parents of 507 children enrolled at the centers (81% of possible participants) provided consent over a 3-year time span. Information provided by center administrators indicated comparable age, race, and SES characteristics for participants and nonparticipants. The ethnic composition of the sample was similar to that of the county according to the 2000 census (61% Caucasian, 33% African American, and 6% other ethnicity). Single-parent households were a minority (30%), and most families (98.7%) had at least one parent who was employed or a student. Among families with at least one employed adult, SES was measured using occupational prestige scores based on parents' reported employment (Entwisle & Astone, 1994). Scores ranged from 25 (e.g., unskilled labor, janitor) to 93 (professional), with a median of 68.

Because of the time and labor required to collect the physiological and relationship data, we selected a subgroup of approximately one third of the participants (five to six classrooms per year in each of 3 years) as a *focus sample* for the more labor-intensive portions of the study. Parent, teacher, and classroom-level data were collected from all the classrooms each year. Children in the focus classrooms also provided saliva samples, were interviewed about their relationships with their teachers, and participated in the individual challenge and teacher–child interaction sessions. This study uses only information collected from the focus sample.

In the 1st year of the study, focus classrooms were selected on the basis of informal judgments of quality to take advantage of the broadest possible range of child-care environments. In subsequent years, classrooms were selected to maximize the number of different classes and teachers involved across the 3 years of the study. Classrooms in 2 of the 12 centers never served as focus classrooms at the request of center administrators. Children attending the 2 centers not participating in the physiological and teacher–child assessment portions of the study differed from the rest of the sample only in maternal education, with mothers in the nonfocus centers reporting higher education levels than mothers in focus centers (*Ms* = 5.07 and 4.38, respectively, on a 6-point scale). Five classrooms were used twice across the 3 years of the study, but these classrooms had different teachers and children each year.

The resulting focus sample consisted of 191 children (90 girls) ranging in age from 43 to 67 months ($M = 53$, $SD = 4.1$ months). The focus sample was 66% Caucasian, 25% African American, and 9% mixed or other racial group. Focus and nonfocus samples differed by age and race, with focus sample children being older ($M = 53$ months vs. 52 months), $F(1, 506) = 10.57$, $p = .001$, and less likely to be African American (25% vs. 38%; $\chi^2 = 9.02$, $p < .05$).

Procedures

Saliva collection procedures. Children provided saliva samples for cortisol analysis in two settings. First, to assess morning and afternoon cortisol levels, and morning to afternoon cortisol changes, samples were collected in children's classrooms in winter (February) and spring (May). Additionally, children individually participated in an out-of-class assessment consisting of a series of mildly challenging tasks for 30 min (challenge task) followed by an interaction with their teacher for approximately 20 min (teacher–child interaction). The challenge task and teacher–child interaction sessions took place in the spring in a familiar quiet room in the center (e.g., a library or an unused classroom). Children provided samples immediately before (*pretask*) and following (*posttask*) the challenge task and again after the teacher–child interaction (*postinteraction*).

All saliva samples were collected at least 30 min after children had consumed any food. Twenty minutes prior to sample collections, children drank a cup of water (4–8 oz) to rinse the oral mucosa free of food residue and particulate matter and to increase hydration. Prior to the winter saliva collection, researchers taught children to provide unstimulated saliva by passive drool into 3-oz plastic cups. Immediately following each sample collection, researchers poured the saliva from the cups into 2-ml plastic cryogenic vials. Samples were sealed in plastic storage bags and placed on ice for transport to a storage freezer, where they remained at −20°C until shipped by overnight delivery on dry ice to Salimetrics Laboratories (State College, PA), where samples were stored at −80°C until assayed.

Morning, afternoon, and daily cortisol change. For classroom samples, children sat in small groups (four to six) at a table supervised by research assistants. Morning saliva collection occurred between 8:00 and 11:00 a.m., with 85% being collected immediately before children had morning snack between 8:30 and 9:30 a.m. ($M = $ 9:00 a.m.). There were no significant differences in a.m. or cortisol change scores for samples collected within this time frame and those collected slightly earlier or later. Following the logic of Shirtcliff, Granger, Booth, and Johnson (2005), winter and spring values were averaged to form morning and afternoon indexes of cortisol for primary analyses (*average daily cortisol change*). For children with full a.m. and p.m. cortisol data from only one collection day, the single a.m. and p.m. cortisol values were used, resulting in an n of 182 children. Unless otherwise specified, the average daily cortisol change was used in analyses.

Due to schedule variations and constraints at different centers, p.m. saliva collection times ranged from 1:00 to 4:00 p.m. and time between a.m. and p.m. samples varied widely (range = 3–7.25 hr, $M = 5.5$ hr, $SD = .75$ hr). Longer times between a.m. and p.m. sample collections were associated with greater cortisol increases across the day ($r = .16$, $p < .05$). Also because of scheduling constraints, 59% of afternoon saliva samples were collected within 30 min of children waking from nap. Consistent with previous findings (Watamura et al., 2002), cortisol levels were slightly lower in samples collected shortly after naptime (within 30 min, $M = .17$) than in samples collected later in the afternoon ($M = .20$), $F(1, 181) = 3.78$, $p < .10$. Nap duration (estimated from schedules provided by the centers) was associated with afternoon cortisol levels ($r = .21$, $p < .01$) and average daily cortisol change ($r = .22$, $p < .01$). Observer ratings of rest quality during naptime were collected in Year 3 of the study, but rest quality ratings were not significantly related to p.m. cortisol values or to daily change.

Challenge task. Children participated in a series of five developmentally salient tasks intended to provoke mild stress, frustration, or disappointment (Stansbury & Gunnar, 1994). Research assistants generated a randomized list of participating children from each classroom to determine the order of child participation. All children were eager to participate in the activity and no child declined. For all but 3 children, challenge task assessments occurred in the morning (M start time = 9:30 a.m., $SD = 43$ min). Children were accompanied to a room in the center by a familiar research assistant, seated at a small table, and immediately asked to provide a saliva sample (*prechallenge*). Children then participated in the challenge tasks, which consisted of a coordination game in which they were asked to drop plastic bears through a small hole in a canister, a disappointment experience in which they expected to receive an attractive toy as a prize but were given a broken toy instead (Cole, Zahn-Waxler, & Smith, 1994), an impossible puzzle task (Smiley & Dweck, 1994), a delay of gratification task (Kochanska & Aksan, 1995), and an inhibitory motor activity task (Kochanska, Murray, & Harlen, 2000). The total time to complete all tasks was approximately 30 min ($M = 31.8$ min, range = 24–43 min). Following the challenge tasks, children provided a second saliva sample (*postchallenge*). *Challenge change* cortisol was computed as postchallenge cortisol − prechallenge cortisol.

Teacher–child interaction session. Immediately after the postchallenge saliva collection, the child's teacher came into the room to interact with the child in two tasks intended to be nonstressful. First, teachers were asked to guide the child in duplicating a printed pattern with colored blocks, and the teacher and child were left alone for 5 min to complete the task. When the researcher returned to the room, he or she removed the blocks and pattern and gave the teacher a picture book with no printed text (Mayer & Mayer, 1975) to "read" with the child. After the teacher and child finished the book, the teacher returned to the classroom and the child provided a third saliva sample (postinteraction). On average, about 30 min elapsed between postchallenge and postinteraction saliva collections ($M = 29$ min, range = 19–40 min). After the final saliva collection, researchers escorted the child back to the classroom. *Interaction change* cortisol was computed as postinteraction cortisol − postchallenge cortisol.

Behavioral and Relationship Assessments

Teacher–child relationship quality. Teachers completed the Student–Teacher Relationship Scale (STRS; Pianta, Steinberg, & Rollins, 1995). The STRS contains 26 items assessing teachers' perceptions of relationships with individual children. Items are rated on 5-point scales. Following Pianta et al. (1995), three relationship scales were derived: *closeness* (11 items; $\alpha = .79$; e.g., "I share an affectionate, warm relationship with this child"), *conflict* (12 items; $\alpha = .90$; e.g., "This child and I always seem to be struggling with each other"), and overdependence or *clingy* (5 items; $\alpha = .73$; e.g., "This child asks for my help when he/she doesn't really need it"). Thirteen of 16 lead teachers completed questionnaires about their relationships with 155 participating children.

Child perceptions of relationship quality. Children's perceptions of their relationships with their lead teachers were assessed in individual interviews using the Feelings About My School and Teacher (FAMST) interview (Payne, 2003). Children participated in the FAMST interviews during the spring of the academic year. The FAMST is based on a modification of the Feelings About Myself and Peers (Meece, Colwell, & Mize, 2007) and the Berkeley Puppet interviews (Measelle, Ablow, Cowan, & Cowan, 1998). Representative items include, "Does [child's teacher] smile at you?" and "Do you like [teacher]?" For most questions, children answered verbally and by pointing to cards on which were mounted no, a few, or many milk bottle caps, corresponding to *not at all*, *some or a little bit*, and *a lot*, respectively. Ten items relating to the child's evaluation of his or her relationship with the teacher were aggregated to form a single scale with higher values (3s) reflecting more negative assessments (child-reported negativity, $\alpha = .69$). Pilot testing ($n = 19$) indicated adequate test–retest reliability (.81) over 2 weeks (Payne, 2003).

Child-level variables. Parents reported on temperament using the Children's Behavior Questionnaire (Rothbart, Ahadi, Hershey, & Fisher, 2001). Temperament dimensions examined in this study were shyness ($\alpha = .80$), fearfulness ($\alpha = .69$), and surgency (a composite of the high pleasure seeking, impulsive, high activity level, and [reversed] shyness scales; $\alpha = .70$). Parent evaluations of child temperament were available from 153 parents of focus sample children. Means for parent-reported temperament variables were similar to those reported in Rothbart et al. (2001). Additional child-level variables examined as potential influences on HPA activity included sex, age, and family SES.

Classroom-level variables. Group size was computed as number of children on class rolls plus the number of teachers typically present as reported by observers (Legendre, 2003). Teachers' insensitivity at the classroom level was assessed using observer reports on the Caregiver Interaction Scale (CIS; Arnett, 1989); the CIS consists of 26 items assessing teacher insensitivity (e.g., "threatens children to control them," and "speaks warmly to the children" [reverse scored]) rated on 4-point scales. Interrater reliability based on 40% of the classrooms in the study was adequate ($\rho_1 = .81$, $p < .001$) and internal consistency was good ($\alpha = .96$). Most teachers were rated as moderately sensitive at the classroom level ($M = 2.13$). However, teachers for 15% of the sample ($n = 3$ teachers) received average ratings greater than 3 on the scale on which 4 represented maximum insensitivity.

Measurement-level variables. On the 2 classroom saliva collection days, parents reported children's wake-up times as they dropped their child off at child care to control for diurnal cortisol patterns. Because some children carpooled or were bussed to the centers, wake-up times were available for only 90 of 164 children providing samples in the winter (55%) and 114 of 166 in the spring (69%). For children with missing wake-up data, we substituted an estimated wake-up time based on the average of wake-up times reported by parents on other saliva collection days and on questionnaires ($\alpha = .83$). There were no significant differences in any study variables between children with actual and substituted wake-up times. Wake-up times were typically not collected on the days when children participated in the out-of-class activities. To control for diurnal cortisol fluctuations for the out-of-class teacher–child interaction analysis, we used the average of available wake-up times reported by parents on saliva collection days and questionnaires.

Salivary Cortisol Determination

All samples were assayed for salivary cortisol using a highly sensitive enzyme immunoassay U.S. Food and Drug Administration (510k) cleared for use as an in vitro diagnostic measure of adrenal function (Salimetrics). The test used 25 μl of saliva, had a lower limit of sensitivity of 0.007 μg/dl, range of sensitivity from 0.007 to 1.8 μg/dl, and average intra- and interassay coefficients of variation of less than 5% and 10%. The average of duplicate assays for each sample was used in all analyses and units are reported in μg/dl (micrograms per deciliter). Cortisol values were positively skewed and subject to logarithmic transformation ($\log_{10}$). All analyses were performed using transformed cortisol values, but to ease interpretation, untransformed μg/dl units are reported in the text, tables, and figures.

Analytical Strategy

The data analyzed in this study represent multiple layers of information (i.e., repeated cortisol measurements from children sharing teacher and classroom influences). Given the nested nature of the data, we selected hierarchical multivariate linear modeling (HMLM; Raudenbush & Bryk, 2002; Raudenbush, Bryk, Cheong, & Congdon, 2004) to examine our primary research questions. HMLM uses multiple covariance matrices derived from different levels of data to accommodate repeated measurements within individuals who share group membership.

Results

Descriptive Analyses

Average daily cortisol change. Some children were absent or only attended half-day on days saliva was collected, so complete cortisol data were not available for all children (8%–10% missing at each collection). Data from three additional children were excluded because extreme values suggested interference or contamination. In winter and spring there were, respectively, 164 and 166 children with both morning and afternoon cortisol data. On average, children's cortisol levels did not change across the child-care days for either the winter or the spring assessments (see Table 1). As expected, however, there was considerable variation among children, with 51.2% and 45.8% showing cortisol increases greater than 1 *SD* of the mean across the day in winter and spring, respectively. Some children (29%) exhibited cortisol increases at both assessments. Winter and spring morning cortisol values were significantly associated ($r = .30$, $p < .001$), but afternoon values were only marginally related ($r = .13$, $p = .10$).

Challenge and interaction task cortisol. One hundred ninety-one children participated in the challenge task procedure. Five children were either unwilling (2) or unable (3) to give sufficient saliva volume for analysis. Four children had at least one extreme cortisol value (> 3 *SD* above the mean) excluded from the data. Descriptive information about challenge task cortisol values is given in Table 1. A repeated measures analysis of variance confirmed that cortisol levels declined, with postchallenge cortisol significantly lower than prechallenge, $F(1, 180) = 69.14$, $p < .001$, and postinteraction cortisol significantly lower than both pre- and postchallenge levels, $Fs(1, 180) = 69.65$ and 12.39, respectively, both $ps < .01$.

Relationship measures. In general, teachers described relationships with children as very close and relatively free of conflict, and children were seen as being moderately clingy in the relationships (see Table 1). Children's responses to the FAMST suggested that they saw their relationships with teachers as being of moderate quality. Teacher-rated closeness was negatively skewed and a quadratic transformation was used to normalize data. Child reports of negative relationships with teachers had a positive skew, and a $\log_{10}$ transformation was applied. Children and teachers agreed modestly about the quality of their relationships (see Table 2).

Hierarchical Analyses: Relationship Quality and Cortisol

Repeated measures hierarchical linear modeling (HLM 6; Raudenbush et al., 2004) was used to examine whether cortisol changes across the day and across the teacher–child interaction were associated with teacher–child relationship quality. Bivariate correlations revealed associations between cortisol and time since waking for the a.m., p.m., and prechallenge samples ($rs = .35$, .49, and .14, $ps < .001$, .001, and .10, respectively). Additionally, an association at the trend level was found for parent-reported fearful temperament and cortisol change across the challenge and teacher–child interaction tasks (see Table 3). Consequentially, time since

Group size	16	(17)		11 to 24
Teacher insensitive	16	(2.04)		1.31 to 3.38

[a]Cortisol values indicate mean of duplicate assay values in μg/dl prior to logarithmic transformation to correct skew. [b]Mean is hours and minutes between child wake up and saliva collection averaged over winter and spring. [c]Does not include families reporting that there were no employed adults in their households.

waking and fearfulness were controlled in the HLM models.

The HMLM analysis used multiple data covariance matrices to examine associations across measurement (Level 1), child (Level 2), and classroom (Level 3) influences. Level 1 data (measurement level) consisted of the cortisol levels at each assessment point as the outcome variable (each assessment occupied one row in the data set), along with the time since waking for each sample collected, and to assess the change (slope) across the interval of interest (e.g., a.m. to p.m.; postchallenge to postinteraction),.a dummy-coded indicator variable for the measurement of interest (e.g., the afternoon cortisol level for the average daily change analysis; see Raudenbush et al., 2004). The second level (child level) consisted of data describing the teacher–child relationship, sex, and parent-rated fearful temperament. Level 2 (child level) variables were modeled to predict both Level 1 intercept values and the slope (cortisol change) for the time period of interest (morning to afternoon or across the teacher–child interaction). Because different numbers of teachers and children reported on relationship quality, separate HMLM analyses were performed for the teacher and child relationship reports (*ns* = 155 and 176, respectively). Level 3 (classroom level) variables included classroom group size and teacher sensitivity.

Relationships and daily cortisol. Teacher reports of child clinginess were related to higher afternoon cortisol levels and average daily cortisol change. Results of the HMLM analyses confirmed that these associations (see Table 4) were independent of classroom, individual child, and other relationship measures. No other teacher- or child-rated relationship

variables were associated with average daily cortisol change.

Because of the potential influence of nap variables on afternoon cortisol levels, we tested a separate HMLM model with time since waking from nap in Level 2 and classroom nap duration in Level 3. Patterns of associations between relationship variables and average daily cortisol change were identical in the two models. For parsimony, we only report the results for the model without the nap variables.

Relationships and cortisol during challenge and teacher–child interaction. As seen in Table 3, children with more positive relationships with teachers (closer, less conflict, and less negative) began the challenge procedure with higher cortisol levels. Children with whom teachers reported more conflict and less closeness had greater cortisol *increases* across the teacher–child interaction (see Table 3). HMLM analyses (presented in Table 5) indicated that only teacher–child conflict predicted cortisol increases during the interaction session when classroom and child-level variables were included in the model.

Discussion

Within the past two decades, methodological advances in the noninvasive measurement of individual differences and intraindividual change in the psychobiology of stress have enabled developmental science to translate research with animals (Hofer, 2004; Meaney, 2005) into a basic understanding of early caregiving effects on children's physiology and behavior. Given the nature of the basic work with animals, it is not surprising that much of the research effort with children has focused on various aspects of mother–child relationship quality such as attachment (Ahnert, Gunnar, Lamb, & Barthel, 2004), conflict (Granger, Weisz, McCracken, Ikeda, & Douglas, 1996), and maternal behavior (Jones et al., 1997). Other research has examined differences between extreme groups defined by "natural experiments," such as child maltreatment and neglect (Cicchetti & Rogosch, 2001) and adoption and foster parenting (Dozier et al., 2006; Gunnar, Morison, Chisholm, & Schuder, 2001). This study extends this translational research by showing that relationships with care providers in out-of-home child-care settings during early childhood contribute to variability in children's HPA activity. Specifically, teacher reports of child overdependence predicted increases in cortisol levels across the child-care day, and reports of teacher–child relationship conflict predicted cortisol increases during a teacher–child interaction session.

Table 3
Correlations Among Cortisol and Relationship, Child, and Classroom Variables

Cortisol	Teacher–child relationship quality				Classroom level		Individual child				
	Teacher-reported close	Teacher-reported clingy	Teacher-reported conflict	Child-reported negativity	Groupsize	Teacher insensitive	Fearful	Shy	Surgent	Socioeconomic status	Age

Importantly, these associations persisted when controlling for child-, classroom-, and measurement-level factors known to influence variation in HPA activity.

Consistent with previous studies, approximately half of the children showed cortisol increases across the day at each of two assessments. However, descriptive analyses suggested considerable within-child variability in cortisol patterns, with only 29% of children experiencing cortisol increases across the day in both winter and spring. Morning cortisol had moderate intraindividual stability from winter to spring; afternoon values did not. These findings highlight the contextual sensitivity of the HPA axis (Flinn, 1999; Sapolsky, 2004). Shirtcliff et al. (2005) estimated that about 70% of variance in cortisol is attributable to situational influences. This study suggests that teacher–child relationship characteristics may be a contextual contributor to cortisol variability.

Teacher–Child Relationships as Contextual Influences

Different aspects of the teacher–child relationship were associated with HPA axis activation in different settings. Children rated by teachers as clingy or overdependent showed increases in cortisol over the day in the classroom. In contrast, children in more conflicted relationships showed elevated cortisol when interacting with the teacher outside of the classroom. In classrooms, children may be able to avoid interacting with teachers with whom they experience relationship difficulties. In the out-of-class activity, however, interaction was unavoidable. Previous research demonstrates that episodes of parent'–child conflict can be accompanied or followed by cortisol increases (Flinn, 1999; Granger et al., 1998), especially for children who perceive a lack of social control (Granger, Weisz, & Kauneckis, 1994). The animal literature suggests that subordinate, rather than dominant, members of dyads are more likely to experience HPA axis activation to conflict (Haller, Kiem, & Makara, 1996; Loving, Heffner, Kiecolt-Glaser, & Malarkey, 2004; Sapolsky, 2004). Certainly, children were the less powerful partners in the dyadic interaction sessions, and some children may have experienced these interactions as stressful, though they were not intended to be so.

The hypothesis that positive teacher–child relationships would predict decreases in cortisol across the day and during teacher–child interaction received modest support. Low conflict was related to greater *decreases* in cortisol across the teacher–child interaction, whereas teacher-reported closeness and child reports of less negativity in the relationship

were marginally related to declines in cortisol during teacher–child interaction in bivariate analyses. When controlling for other child and classroom variables in the HMLM models, only teacher–child conflict predicted cortisol change during the teacher–child interaction. The modest links between teacher-reported closeness and children's cortisol levels may be explained by low variability in closeness ratings; teachers may be constrained by social desirability to describe relationships with children under their care in positive terms. Alternative methods for quantifying positive aspects of teacher–child relationships, such as observation of classroom interactions (Howes et al., 1998), should be explored.

Alternative Hypotheses

Temperament. It is possible that teacher-reported clinginess reflects assessments of behavioral temperament rather than relationship characteristics. Children described as clingy by teachers may lack confidence in their abilities to cope with challenges in the classroom. Similarly, children with whom teachers said they had more conflict may have been

the more difficult or active children who felt constrained in the interaction session. This interpretation is consistent with previous research linking temperament to children's cortisol at child care (Dettling et al., 1999; Gunnar, Sebanc, Tout, Donzella, & van Dulmen, 2003; Watamura et al., 2002).

By and large, however, the pattern of associations among study variables does not support the temperament interpretation. Had teachers based their relationship ratings on children's temperament, some correlations between relationship quality and parent temperament ratings would be expected. However, there was no significant correlation between any teacher-reported relationship scale and any parent-reported temperament dimension. In contrast, children and teachers agreed modestly about the quality of their relationships, and children rated relationships with less sensitive teachers as being more negative. This pattern suggests that both teachers' and children's reports captured some specifically dyadic aspects of their relationships.

Of the three temperament qualities examined in this study, only fearfulness was associated with any cortisol measure: More fearful children showed a trend toward greater decreases in cortisol over both the challenge task and the teacher – child interaction session. The nonsignificant associations between child characteristics and HPA activity are consistent with the notion that context is a stronger influence on cortisol than are individuals' traits (Shirtcliff et al., 2005), but contrary to some previous research reporting that children who are shy (Gunnar et al., 1997), have poorer effortful control, or have greater negative emotionality (Dettling et al., 1999; Dettling et al., 2000; Gunnar et al., 2003) are more likely to experience cortisol increases over the day at child care. This discrepancy may be attributed to measurement and sample characteristics. Some previous studies have used teacher reports of temperament (Gunnar et al., 2003; Watamura et al., 2002), or composites of teacher and parent reports (Dettling et al., 2000), and teacher reports may be more likely than parent reports (Manz, Fantuzzo, & McDermott, 1999) to correspond to children's behavioral and emotional characteristics at school (Culp, Howell, Culp, & Blankemeyer, 2001). However, parent reports of low effortful control and impulsivity also have been linked to cortisol increases across the day in children attending a university child-care program (Dettling et al., 1999). Parents in the current sample represented a wide range of economic and educational backgrounds and may have interpreted the temperament questionnaire differently than did parents in previous studies. In particular, the moderate internal reliability for the temperament scales in this study may have limited the ability to detect associations with children's cortisol.

Age. Younger preschool children are more likely to experience increases in cortisol over the day in child-care settings (Dettling et al., 1999), especially younger children in mixed-age groups (Legendre, 2003). Age was not associated with any cortisol measures in this study, perhaps because of the restricted age range of children. However, age may indirectly influence cortisol through children's experiences with their teachers. Teachers rated relationships with older children as being closer and less conflicted and older children were marginally less clingy than younger children. Examining age differences in social behavior may inform our understanding of children's physiological experience in classrooms.

Methodological influences relating to the teacher – child interaction. The fact that the challenge task always preceded the teacher – child interaction session is both a strength and a weakness of the current study. On the one hand, carryover effects of stress children may have experienced during the challenge task could influence cortisol during the teacher – child interaction. On the other hand, all children were exposed to a comparable experience prior to interacting with their teachers. This consistency allows for better isolation of the effects of the teacher – child relationship on cortisol than would be possible if children had been in their classrooms prior to the interaction.

Another methodological consideration is the timing of the out-of-class assessment. In this study, the teacher – child interaction occurred in the morning. Because of the typical decrease in cortisol levels across the day, the HPA axis may be more sensitive to stressors in the afternoon than in the morning (Dickerson & Kemeny, 2004). Higher morning cortisol may obscure stressor effects (Ramsay & Lewis, 2003) in part because of stronger genetic effects on morning as compared to afternoon cortisol levels (Bartels, de Geus, Kirschbaum, Sluyter, & Boomsma, 2003). Results may have been different had the challenge and interaction procedures occurred in the afternoon when, theoretically, the influence of context would have been more powerful. However, because of the timing of naps, snacks, variation in parent pickup time, and child-care staff shift changes, staging the teacher – child interaction in the afternoon was logistically impossible.

Classroom influences. Of all study variables, group size had the most consistent pattern of bivariate associations with cortisol levels and changes. Children in classrooms with more members had marginally lower morning cortisol but significantly higher afternoon cortisol and greater cortisol increases across the day. The afternoon and morning to afternoon cortisol change data are consistent with previous research showing higher cortisol in toddlers in larger groups (Legendre, 2003) and with studies of the effects of crowding on stress and HPA axis functioning (Nelson, 2005; Thiessen & Rogers, 1961). Larger groups are louder, offer more opportunities for conflict and competition for scarce resources (including teachers' time), and are more stressful for teachers (French, 1993). Teachers with larger classrooms were rated by observers as less sensitive to children's needs. Thus, class size may operate directly and indirectly (through teacher behavior) to influence children's cortisol.

More unexpected were associations between group size and higher cortisol in the out-of-class activity. Because each child had been out of the classroom for about half an hour prior to beginning the teacher interaction session, direct effects of classroom factors on cortisol during teacher–child interaction were expected to be minimal. Even so, children in larger groups had greater increases in cortisol over the challenge task and higher cortisol levels after the challenge and teacher interaction procedures. Stressful classroom events prior to the challenge procedure, which may have occurred more often in larger groups, may have continued to influence children's HPA axis activity even after children had been out of the classroom for half an hour or more. This seems an unlikely explanation, however, given that pre-challenge cortisol was not associated with group size. Perhaps, children in smaller groups develop better coping skills, more confidence, or are less reactive to stressful situations, all of which would support better adaptation to unexpected challenges.

Why children in larger groups had lower morning cortisol levels is not obvious, and, given the modest magnitude, it may be spurious. In contrast, some studies have documented low morning cortisol for children in center-based child care (Dettling et al.; Dettling et al., 2000), which affords some degree of confidence in the finding. The explanation may lie in family conditions that covary with child-care arrangements (NICHD Early Child Care Research Network, 1997). Perhaps parents who reported to work earlier tended to place their children in child-care arrangements serving larger groups so that children in larger groups were awake longer prior to the morning saliva collections. As expected, children in our study who had been awake longer had lower cortisol levels at the morning assessments. However, controlling for the amount of time children had been awake at the morning collections did not affect the magnitude of the association between group size and any cortisol value. The link between group size and lower morning cortisol could be a concern if it suggests disruption of the normal diurnal pattern (Gunnar & Vasquez, 2001).

Conclusions and Implications

This study used a community-based sample to replicate findings that a substantial proportion of preschool-aged children in full-day child care experience an afternoon cortisol increase, rather than decrease, across the day. We found that aspects of the teacher–child relationship predicted cortisol increases both in the classroom and during a dyadic teacher–child interaction outside the classroom, even after controlling for measurement-, child-, and classroom-level factors previously found to influence cortisol. Previous research demonstrates the importance of teacher–child relationships for young children's school and behavioral adjustment concurrently (Birch & Ladd, 1997) and longitudinally to early adolescence (Hamre & Pianta, 2001). This study demonstrated associations between teacher–child relationships and children's physiological functioning.

Whether elevated cortisol functions as more than simply a marker of children's immediate discomfort, anxiety, or exertion is not clear. Cortisol elevations in many circumstances are adaptive (Sapolsky, 2004) and a marker of social competence, particularly in new situations (Gunnar et al., 1997). Higher baseline cortisol levels among preschool-aged children predict internalizing symptoms in elementary school, even after controlling for early behavioral evidence of anxious–fearful behavior (Smider et al., 2002). Conversely, low baseline cortisol is a robust psychophysiological correlate of antisocial behavior (McBurnett, Lahey, Rathouz, & Loeber, 2000; Scarpa & Raine, 2006). Low morning cortisol appears to be a marker of current or previous adversity and is characteristic of adults with a history of childhood trauma (Weissbecker, Floyd, Dedert, Salmon, & Sephton, 2006) and children growing up in Eastern European orphanages (see Gunnar & Vazquez, 2001, for a review). Gunnar and Vasquez (2001) have argued that low morning cortisol, or hypocortisolism, in young children can reflect a downregulation of the HPA axis in response to chronic activation and appears to be a risk factor for problems in several domains, including attentional, behavioral, and health-related conditions. In contrast, animal studies suggest moderate levels of cortisol are necessary for supporting neural development (de Kloet, Oitzl, & Joëls, 1999). Identifying optimal cortisol levels in children and factors that contribute to healthy HPA axis functioning constitutes an important agenda for developmental research.

The modest across-time stability of cortisol measures in this study and the high moment-to-moment variability in cortisol in general (Shirtcliff et al., 2005) likely reflect unmeasured and transient experiences. In the child-care setting, these experiences would include peer conflict, injuries, and discipline encounters. The apparent importance of such events suggests the need for more fine-grained, moment-to-moment analysis of children's experiences in child care in conjunction with concurrent collection of multiple saliva samples to chart experience–cortisol links (Coste, Strauch, Letrait, & Bertagna, 1994; Flinn, 1999). This approach would be consistent with the view that more global aspects of child-care environments, such as group size and teacher sensitivity, are best conceptualized in terms of how they influence children's actual experiences (Pianta, 1999). Cortisol fluctuations in child care most likely reflect interplay between individual child, teacher, peer, and classroom influences.

Some have argued that concurrent examination of multiple physiological systems is necessary to fully understand the significance of these systems and their disrupted functioning for children's development (Bauer, Quas, & Boyce, 2002; Granger & Kivlighan, 2003). In particular, asynchrony in reactivity of the sympathetic-adrenal-medullary (SAM) and the HPA systems may mark or condition risk for adjustment problems (Bauer et al., 2002). The development of procedures to measure alpha-amylase, a marker of SAM activation (Chatterton, Vogelsong, Lu, Ellman, & Hudgens, 1996), in saliva makes it feasible to noninvasively asses both HPA and SAM activity in young children (Granger et al., 2006). Future research should incorporate other aspects of children's physiological functioning to better understand how child care influences children.

This study sheds additional light on an as yet incompletely understood phenomenon—disruption of the typical pattern of HPA activity among many young children attending full-day child care. Additionally, the data begin to situate child care–cortisol research in the context of a broader conceptual and empirical literature on the role of relationships in shaping baseline functioning and reactivity of physiological systems in developing organisms (Sanchez, Ladd, & Plotsky, 2001).

Longitudinal Effects of Student Mobility on Three Dimensions of Elementary School Engagement

Diana H. Gruman

University of Washington

Working within the developmental science research framework, this study sought to capture a dynamic and complex view of student mobility. Second- through fifth-grade data ($N = 1{,}003$, predominantly Caucasian) were drawn from a longitudinal study, and growth curve analyses allowed for the examination of mobility effects within the context of other factors that put children at risk, including behavior problems and family stress. School changes predicted declines in academic performance and classroom participation but not positive attitude toward school. Time-varying factors such as peer acceptance and teacher support had a positive influence on the growth trajectories of child outcomes. Additionally, teacher support had a particularly strong influence on positive attitudes toward school among children who had more school changes.

Educators and parents have long voiced concern about the effects of school enrollment changes on children's adjustment and achievement (Blane, Pilling, & Fogelman, 1985; Cramer & Dorsey, 1970), and accordingly, the consequences of student mobility have been the focus of numerous studies. A clear finding across this literature is that student mobility, defined as making a school enrollment change at a time not required by the grade structure of the school system, is associated with numerous other risk factors such as poverty, stressful life events (e.g., divorce), poor initial school performance, and a tendency to make additional enrollment changes during subsequent school years (Alexander, Entwisle, & Dauber, 1996; Eckenrode, Rowe, Laird, & Brathwaite, 1995; Kerbow, 1996; Nelson, Simoni, & Adelman, 1996; Pribesh & Downey, 1999). Given the intertwined nature of these factors, it can be difficult to isolate the impact of mobility from other factors that put children at risk for school problems. In a seminal article, Schaller (1976) cautioned researchers to control for preexisting differences when examining the effects of mobility, but not all subsequent researchers have heeded his warning.

Among the studies that have used controls, results suggest that student mobility has a negative effect on school performance, above and beyond the impact of other stressful features of a child's life (Astone & McLanahan, 1994; Haveman, Wolfe, & Spaulding, 1991; Heinlein & Shinn, 2000; Ingersoll, Scamman, & Eckerling, 1989). Some of the negative consequences associated with student mobility include: lower math and reading test scores (Mantzicopoulos & Knutson, 2000; Texas Department of Education, 1997), an increased risk of behavior problems (Tucker, Marx, & Long, 1998; Wood, Halfon, Scarlata, Newacheck, & Nessim, 1993), and a higher likelihood of being held back a grade (Simpson & Fowler, 1994; Tucker et al., 1998). Student mobility has also been shown to impact school completion and expected educational attainment (Astone & McLanahan, 1994; Hagan, MacMillan, & Wheaton, 1996; Pribesh & Downey, 1999; Rumberger & Larson, 1998; South, Haynie, & Bose, 2007).

Although a preponderance of the mobility research, and the related area of school transitions research (i.e., the study of scheduled enrollment changes to kindergarten, middle, or high school), has focused on either the experience of adolescents or the transition to kindergarten, the current study examines effects of mobility during the elementary school period. The gap in our knowledge is noteworthy because school mobility during the elementary

school years may be strongly linked to long-term measures of school success, such as high school completion (Alexander et al., 1996; Haveman et al., 1991; Heinlein & Shinn, 2000).

How might enrollment changes made during elementary school influence long-term outcomes? Dropping out of school has been described as a developmental process of disengagement that may have its roots in the earliest grades (Finn, 1989; Rumberger, Larson, Ream, & Palardy, 1999). Research has shown that a scheduled transition to middle school or high school represents a dramatic environmental shift and a potential misfit for students that can begin to deteriorate some students' commitment to and sense of belonging at school (Alspaugh, 1998; Eccles & Midgley, 1990; Seidman & French, 1997). For elementary-age students making unscheduled school changes, this deterioration may be intensified because they typically are not involved in the decision to move and often face the adjustment process without the benefit of planned orientations (Jason et al., 1992). Additionally, researchers have concluded that elementary school mobility may have particularly harmful effects on academic performance because moving disrupts the acquisition of the critical building blocks on which later learning is based (Kerbow, 1996; Lash & Kirkpatrick, 1990).

In the present study, we sought to expand our understanding of how mobility during the elementary school years may contribute to the process of disengagement with school just prior to the significant changes that await children in adolescence. We wanted to improve on prior research and found the developmental science framework (Magnusson & Cairns, 1996) to be an instructive guide in determining our approach. The framework emphasizes that dynamic change occurs when individuals face environmental change, and it is therefore important to study adaptations to change "moment to moment," as the individual interacts with new features of the environment. Capturing the "emergence, dynamics, and pathways of change" in individual development (Magnusson & Cairns, 1996, p. 9) requires an analysis of longitudinal data. Typically, mobility researchers have used cross-sectional and retrospective designs and examined endpoint measures such as high school completion rates. In the context of this study, we chose to examine yearly measures of engagement and school experiences to allow us to consider temporal changes in exacerbating, confounding, and protective variables. We also determined that a multilevel analysis of the data would provide the best means to consider stable child characteristics as well as time-varying covariates that may impact individual students at each occasion of a school transfer (Raudenbush & Bryk, 2002; Snijders & Bosker, 1999).

Within the developmental science framework, it is recommended that researchers view the individual within a complex set of systems, taking into account the reciprocal process of an individual's interaction with the environment. Specifically, it is proposed that "variables in the developmental processes of individuals cannot be effectively studied if they are divorced from the social and environmental contexts in which they occur" (Magnusson & Cairns, 1996, p. 13). In the current study, we examine data from child, family, and school systems and focus attention on how school engagement outcomes are influenced by factors present in the school environment.

Among the challenges of conducting the type of research outlined in the developmental science framework is the retention of subjects (Magnusson & Cairns, 1996). Indeed, a number of the previous longitudinal studies of at-risk and mobile elementary-age students have lost between 20% and 25% of the original study population (see Alexander et al., 1996; Heinlein & Shinn, 2000; Temple & Reynolds, 1999). To ensure that the experiences of students who may be the most negatively affected by mobility were included, we used data from a study in which 94% of subjects were retained through the elementary grades (Fleming, Harachi, Catalano, Haggerty, & Abbott, 2001; Haggerty, Catalano, Harachi, & Abbott, 1998).

The Impact of Social Ties: Coleman's Theory of Social Capital and Vygotsky's Theory of Appropriation

One of the theories used commonly in the literature to explain the link between mobility and poor educational outcomes is the "social capital" theory of Coleman (1988, 1990). Closely related to the economic concepts of human and financial capital, social capital represents the relationship between the parents and the child and the network of relationships between parents, friends, and community members that may provide support to the family (Coleman, 1988). According to the theory, moving harms children's achievement because social ties are broken, thereby disrupting the exchange of social capital in the network. A number of controlled studies have drawn on Coleman's theory to explain how mobility, social capital, and achievement may be related (Hagan et al., 1996; Pribesh & Downey, 1999; South et al., 2007; Tucker et al., 1998). Because Coleman proposed a variety of indicators of social capital, each study uses a different measure of social capital.

In their study of mobility and high school dropout rates, Hagan et al. (1996) focused on the quality of the child's relationship with their parents and the father's level of participation in the family. They determined that "mother's support and father's participation are important sources of social capital that can mitigate the disruptive effects of family migration" (p. 381). In an attempt to broaden the definition to include social ties outside the family, Pribesh and Downey (1999) used six different measures of social capital, including participation in high school extracurricular activities, the frequency with which students discuss course planning with peers or parents, and the amount of contact parents have with other parents and school personnel. Moves were associated with declines in nearly all these measures of social capital, although higher levels of social capital appeared to buffer the negative effect of moving on test scores and educational attainment goals. Pribesh and Downey were also concerned about the impact of family stress experiences as a proxy for diminished social support. They determined that students whose parents divorced or who had one parent marry or die experienced declines in test scores independent of other variables. Finally, South et al. (2007) examined parent–child social ties, as well as other factors that might explain the higher dropout rates among mobile high school students, including psychological well-being (e.g., depression, self-esteem), school engagement, and peer friendships. They determined that for adolescents, lower levels of "peer network structure," measured by a student's place in a peer network and the density of the structure, provided the best explanation of movers' higher dropout rates.

This body of research has expanded our understanding of student mobility in a number of ways. First of all, most of these authors attended to both risk and protective factors in testing the impact of mobility. The typical approach has been to focus on how the severing of ties to familiar people and routines may negatively impact students. Research has shown, however, that not all highly mobile children suffer negative consequences (Kerbow, 1996; Mantzicopoulos & Knutson, 2000; Tucker et al., 1998). One result of the social capital research is that we are beginning to understand more about the factors that protect mobile children from harm following a school change. In particular, social support from family and peers appears to be powerful moderators of outcomes for mobile students. Still absent from the literature is a comprehensive study of the role that teachers play in supporting mobile children.

Additionally, by considering different spheres of influence surrounding the child and defining social capital in multiple ways, the authors who have examined social capital have tried to illuminate the complex relationship between mobility and educational outcomes. This approach has led to greater understanding, for example, of the role of stressful family events, such as divorce, that may operate independently of changing schools to erode the support that children need to succeed in school. Unfortunately, the lack of definitional clarity has been one of the criticisms of social capital theory in recent years (see Durlauf, 1999; Morrow, 1999), leading one author to conclude that social capital is better construed as a "descriptive construct rather than an explanatory model" (Morrow, 1999, p. 760). In the context of the present study, we determined that a test of "social ties" within the school environment was more appropriate than a test of social capital per se. Here, we are interested in how social ties with teachers and peers in the school environment serve to support successful outcomes for students experiencing family stress and/or mobility.

Complementing the perspective of social capital theory, Vygotsky's (1962, 1978) sociocultural theory of "appropriation" describes the processes through which supportive teacher and peer relationships may provide an important positive influence for mobile children. Summarized by Thompson (1998), the model of appropriation "underscores how social interaction provides the medium by which socioemotional skills, understanding, and perspective are jointly created as the child participates with others in shared activity, whether consisting of face-to-face exchanges, collaborative play, or the soothing of fears or distress" (Thompson, 1998, p. 27).

Important from a mobility perspective, Vygotsky emphasized that adaptation to the environment is achieved by social means (Goldstein, 1999; van der Veer & Valsiner, 1994; Wertsch, 1985). When we consider the experience of the child who has just changed schools, perhaps overwhelmed by the new physical space and mourning the loss of friends in a previous school, we expect that there may be a period of adjustment during which time the child may not show signs of academic progress (Kerbow, 1996; Vernberg, 1990). Once past the orientation stage (e.g., becoming acquainted with the schedule of daily activities and academic/behavioral expectations), we hope that a child will not only adapt to the new setting but also begin to develop social and academic skills at the same rate as before moving. Drawing on the theory of appropriation, what creates a bridge between bewilderment and success in the new setting is helpful social contact with a teacher and peers.

Empirical evidence to support the role of social contacts in mitigating stressful life events for children is abundant (DuBois, Felner, Meares, & Krier, 1994;

Garmezy, 1983; Hendershott, 1989; Sandler, Miller, Short, & Wolchik, 1989; Wenz-Gross, Siperstein, Untch, & Widaman, 1997), with research indicating that strong connections among students, teachers, and positive peers facilitate access to social and scholastic activities (Hughes, Cavell, & Willson, 2001; Ladd, Birch, & Buhs, 1999; Ladd & Burgess, 2001; Wentzel, 1997). Research has also shown that student–teacher relationships characterized as supportive, close, or caring, have significant effects on academic motivation, attitude, and engagement in the school environment (Birch & Ladd, 1997; Wentzel, 1997).

In the area of student mobility, studies of the scheduled transition to middle school or high school indicate that support from peers and teachers positively influences the academic and social adjustment of adolescents (Felner, Ginter, & Primavera, 2002; Hirsch & DuBois, 1992; Isakson & Jarvis, 1999; Lord, Eccles, & McCarthy, 1994). As we have mentioned, less is known about the relational factors that influence the school success of elementary school students making unscheduled school changes. For this study, we are interested in the potential protective qualities of peer and teacher relationships for these mobile students.

School Engagement Outcomes and Mobility

What measures of school engagement do we think might be negatively influenced by mobility and positively influenced by supportive peer and teacher relationships? Recognizing that a number of key shifts in children's attitudes and behaviors may occur when they experience enrollment changes in the early years of schooling, we selected three dimensions of engagement to shed light on the academic, affective, and behavioral facets of school success (Finn, 1989; Finn & Rock, 1997). First of all, we include a measure of teacher-rated academic performance in three core curricular areas—reading, math, and language arts—to confirm the results of previous studies (Kerbow, 1996; Tucker et al., 1998). Second, we include a measure of children's attitudes toward school to tap the affective dimension of school engagement (Alexander, Entwisle, & Horsey, 1997). We included an affective measure because mobility has been linked with increased rates of behavior problems (e.g., suspension, disobedience) in elementary-age students (Tucker et al., 1998; Wood et al., 1993), and though as yet untested, we suspect that the increased difficulties that mobile students experience might erode the positive attitudes students hold about school.

Finally, the development of positive classroom behaviors such as participation and cooperation skills may be compromised when children, lacking consistent reinforcement and support, move from setting to setting. Though untested in the context of mobility, we believe that these "deportment" behaviors are worth examining given the empirical support for their influence on academic performance (Alexander, Entwisle, & Dauber, 1993; Alexander et al., 1997; Ladd et al., 1999). We therefore include a scale called "classroom participation" that indicates the extent to which an individual interacts appropriately with teachers and peers in the classroom.

Current Study

The purpose of this study is to open up a more dynamic view of mobility than has previously been attempted, using longitudinal data to explore how mobility during the elementary school years might undermine or erode the skills and attitudes that typically lead to successful school outcomes. Data from second through fifth grades were drawn from an ongoing longitudinal study in which researchers successfully retained a high percentage of subjects (94%) despite a high degree of mobility within the subject pool (Fleming et al., 2001; Haggerty et al., 1998). Within the design, we considered how risk factors as well as protective factors in the school and home environment might influence academic and behavioral outcomes at fifth grade (see model design in Figure 1).

Children who move, especially frequently, also tend to experience other stressors that make them more vulnerable to school failure. Thus, we included measures of additional risk factors (represented on the left side of the model in Figure 1) in our tests of

mobility to understand the stressful context of mobile children's lives. Low socioeconomic status and gender (being male) are included because they have been shown to increase the risks of negative school outcomes for mobile children (Ellickson & McGuigan, 2000; Heinlein & Shinn, 2000; Jason et al., 1992; Mantzicopoulos & Knutson, 2000; Nelson et al., 1996; Tucker et al., 1998; Wood et al., 1993). Initial shy/withdrawn behavior and initial antisocial behavior are included because they have been tied to poor educational outcomes and may hinder the development of relational supports available to mobile students (Coie, Dodge, & Kupersmidt, 1990; Ladd & Burgess, 2001; Wentzel, 1993). We further recognize that when students face chronic stress or concurrent stresses, they have a more difficult time coping (Hetherington, 1979; Hofferth, Boisjoly, & Duncan, 1998; Moore, Vandivere, & Ehrle, 2000; Simmons, Burgeson, Carlton-Ford, & Blyth, 1987; Tucker et al., 1998). We therefore include two variables, total school changes and total stressful life events, to test the cumulative effects of these experiences.

In addition, we included time-varying factors measured at each grade level to determine whether dynamic factors play a role in changing the trajectories of growth for mobile students (Magnusson & Cairns, 1996). Data for these four factors, gathered through child, parent, and teacher surveys, include two risk factors: children's yearly experiences with family stress and school enrollment changes (represented in the top box of the model in Figure 1) and two protective factors: peer acceptance and teacher support (represented in the lower box in Figure 1). The three outcome measures (in the center boxes in Figure 1), representing different behavioral and attitudinal components of school engagement, were taken from teacher and child surveys. These include a measure of teacher-rated academic performance, a measure of classroom participation that indicates that an individual is participating successfully in the academic and social life of the classroom, and a measure of positive attitude toward school to determine how mobility impacts the affective ties that children have toward school. The method of analysis, linear growth curve modeling, allowed us to examine the interactions between the individual, their family circumstances, and their school relationships across time, thereby modeling the complexity of the mechanisms through which mobility may impact school performance and related skills and attitudes (Adelman & Taylor, 1991; Ladd & Burgess, 2001; Reynolds & Bezruczko, 1993).

In summary, this investigation seeks to assess both the short-term effects of mobility, through yearly measures, and trends over multiple years, though cumulative measures. We are further interested in the role that family stress (measured both yearly and cumulatively), teacher support (measured yearly), and peer acceptance (measured yearly) play in influencing student engagement. We sought to answer three questions: First, do experiences with elementary school mobility, measured cumulatively, diminish attitudes toward school and reduce the development of classroom participation and academic performance? Second, do risk factors, including gender, low-income status, antisocial and shy/withdrawn behavior, and overall family stress, play a role in explaining the relationship between mobility and school outcomes? Third, do yearly measures of school change, family stress, peer acceptance, and teacher support impact the development of social and academic outcomes, taking into account other risk factors?

Method

Raising Healthy Children Project

This study analyzed data from the Raising Healthy Children (RHC) project, a prospective longitudinal intervention study conducted by the Social Development Research Group. In the fall of 1993, 10 public elementary schools in a Pacific Northwest suburban school district were selected because they had student populations with high aggregate measures of risk relative to other schools in the district. Risk was based on the percentage of students having below-average standardized reading scores, living in single-parent households, receiving subsidized school lunches, and experiencing high rates of mobility. Eligibility criteria for the sample included: attending a regular education first- or second-grade classroom, remaining in the project school from the time of parental consent (January 1994) through to completion of the first student survey in the spring of 1994, and having a parent who spoke English, Spanish, Vietnamese, or Korean.

Parents of 938 (76%) of the 1,239 eligible students consented to participation. In the 2nd year of the study, second- and third-grade students who had newly enrolled into a project school were also invited to participate in the study, bringing the overall study cohort to 1,040 students. There were no significant differences on basic demographic characteristics between consenting and nonconsenting families. Data in the RHC project were collected on a yearly basis from district records and from annual parent, child, and teacher surveys administered each spring. Parents received a $10 incentive for survey participation, students received a small gift, and teachers received a $5 incentive for the assessment of each consenting student in their classroom. Particular attention was paid to retaining a maximum number of participants, even if they moved out of the state. A 94% retention rate was maintained at the end of the 5th year of data collection, when students were enrolled in fifth or sixth grade.

RHC is a study of the etiology of problem behaviors as well as a randomized test of a multicomponent preventive intervention. The intervention was delivered at five of the project elementary schools and consisted of instructional staff development for teachers, parenting workshops, booster sessions for parents and teens, summer camps and study clubs for students, and home-based case management services for high-risk students who exhibited academic or behavioral problems. Additional details regarding the RHC intervention have been reported by Catalano et al. (2003), Haggerty et al. (1998), and Brown, Catalano, Fleming, Haggerty, and Abbott (2005).

RHC is an ongoing longitudinal intervention study. An experimental/control variable was included originally in the analytic plan for the present study. In this analysis, experimental effects on the outcomes were examined using both correlational methods and hierarchical linear modeling, but at no point during the analytic process was an experimental effect detected. Therefore, data in this present study were pooled and include children in both the experimental and the control conditions.

Sample

Data on students when they were enrolled in Grades 2 through 5 were used for this study. Of the 1,040 children originally enrolled in the RHC project, 37 were removed from the current analysis. First, 9 students who were homeschooled during the elementary grades were eliminated because they had limited teacher data and lacked school-based experiences important in this study. Second, the statistical design required a complete set of time-invariant individual data for each subject, which reduced the study by another 28 students, leaving a total of 1,003 for the present analysis.

The sample contained roughly equal numbers of boys and girls (471 girls and 532 boys), and 35% of parents reported that their families were low income during one of the first 2 years of the study ($n = 355$). In terms of mobility, nearly 50% of children remained in the same school during second through fifth grades ($n = 497$), 33% made one school change ($n = 328$), 13% made two changes, and 5% of the sample made three or more school changes ($n = 47$). For stressful family events, characterized by changes in parental relationships, family experience with job loss, serious accidents or illnesses, or death of a household member, 48% of children ($n = 478$) experienced either zero or one stressful event over the 4-year study period. Twenty-eight percent experienced two or three events ($n = 276$), 14% experienced four or five events ($n = 143$), and 9% ($n = 90$) experienced six or more stressful family events.

In terms of ethnic group composition, the sample represented a population typical of many suburban school districts: 82% ($n = 818$) European American, 7% ($n = 72$) Asian/Pacific Islander, 4% ($n = 43$) Hispanic, 4% ($n = 43$) African American, and 3% ($n = 27$) Native American. The lack of diversity in the sample limited our analysis of race/ethnicity in this study. However, we did examine whether mobility, family stress, and other risk/protective factors were associated with the available categories of race/ethnicity and found that there were no significant unique associations after controlling for low-income status, gender, antisocial, and shy/withdrawn behavior.

Measures

In the following list of measures, items taken from existing measures cite the source; otherwise, the items were created for use in the RHC project. Means, standard deviations, alpha reliabilities, data source, and data collection points are provided in Table 1.

Outcomes

Classroom participation. A nine-item scale assessing classroom participation was drawn from teacher surveys. The scale consists of items derived from the Walker – McConnell Scale of Social Competency and School Adjustment (Walker & McConnell, 1988) and Teacher Observation of Classroom Adaptation – Revised (TOCA – R; Werthamer-Larsson, Kellam, & Ovesen-McGregor, 1990). Yearly alpha reliabilities for Grades 2 through 5 were .91, .90, .90, and .90. Example items include: (a) interacts appropriately with teacher, (b) cooperates with peers in group activities, and (c) listens while others are speaking. The response options for items ranged from either *rarely or never true* to *often true* or *not at all* to *often true*. A mean score was computed across items so that the scale had a range from 1 to 5.

Table 1

Descriptive Statistics for Hierarchical Linear Modeling Analyses

Variable	*M*	*SD*	*N*	α	Data source	Data collection
Time invariant						
Gender	0.53	0.50	1,003		Parent	Year 1 or 2
Low income	0.35	0.48	1,003		Parent	Year 1 or 2
Antisocial	1.24	0.42	1,003	.88	Teacher	Year 2, fall
Shy/withdrawn	1.34	0.40	1,003	.81	Teacher	Year 2, fall
Total school changes	0.74	0.90	1,003		School	Yearly, spring
Total stress	2.14	2.18	1,003		Parent	Yearly, spring
Time varying						
Yearly school change	0.18	0.39	3,917		School	Yearly, spring
Yearly stress	0.58	0.79	3,684		Parent	Yearly, spring
Peer acceptance	0.00	0.85	3,759	.75–.89	Teacher	Yearly, spring
Teacher support	3.46	0.54	3,827	.54–.78	Child	Yearly, spring
Classroom participation	3.80	0.78	3,755	.90–.91	Teacher	Yearly, spring
Attitude toward school	3.15	0.62	3,831	.55–.70	Child	Yearly, spring
Academic performance	3.19	1.23	3,753	.92–.93	Teacher	Yearly, spring

Note. The time-invariant variables were entered at Level 2. The time-varying variables were entered at Level 1.

Positive attitude toward school. A four-item scale assessing a child's attitude toward school was drawn from child surveys administered each year. Items were taken from the Seattle Social Development Project (Hawkins & Catalano, 1990) and the Seattle Personality Questionnaire (SPQ; Kusché & Greenberg, 1988). Items include: (a) Do you think school is fun? (b) Do nice things happen to you at school? (c) Do you feel unhappy at school a lot? (d) Do you look forward to going to school? Response options were *YES, yes, no, NO.* A mean score was computed across items so that the scale had a range from 1 to 4. Though internal consistency was moderate, alpha reliabilities increased as children grew older (α = .55, .62, .70, and .70).

Academic performance. Teacher ratings of a child's academic performance in three content areas (language arts, math, and reading) were collected each year. The 5-point response options for each item were *above average, slightly above average, average, slightly below average,* and *needs improvement.* A scale was created by averaging the three academic areas each year with a range of 1–5. Due to the frequent school changes within the study population (across regions and states), we are unable to use standardized test data without compromising the sample retention rate. However, construct validity of our measure of academic performance is supported by a .79 correlation between this measure and a composite of math and reading scores on the California Test of Basic Skills administered to the students who were still enrolled in the same school district in fourth grade.

Time-Varying Measures

Yearly school changes. A school transfer variable was coded in each of the 4 years as 0 = *no school transfer* and 1 = *one or more school transfers.* Transfers were calculated for the period between June of one school year and June of the next school year using district and school office records.

Yearly family stress. Stressful events in the life of each child were assessed yearly through parent surveys and were summarized into a 0–4 index. The events included: changes in parental relationships, family experience with job loss, serious accidents or illnesses, and death of a household member over the course of the past year.

Teacher support. Four items assessed a child's perception of teacher support. Items were drawn from the Seattle Social Development Project (Hawkins & Catalano, 1990) and were designed to measure prosocial processes in the classroom (Catalano et al., 2005). The items include: (a) Does your teacher notice when you try hard? (b) Does your teacher tell you when you do well? (c) Does your teacher help you when you need it? (d) Do you like your teacher? Response options were *YES, yes, no, NO.* A mean score was computed across items so that the scale had a range from 1 to 4. Though internal consistency was moderate, alpha reliabilities increased as children grew older (αs = .54, .68, .75, and .78).

Peer acceptance. A three-item scale representing level of peer acceptance was drawn from teacher surveys administered each spring. Items were taken from the Walker T Pref. (Walker & McConnell, 1988) and from the TOCA–R (Werthamer-Larsson et al., 1990). The items include: (a) makes friends easily with other children, (b) plays with classmates, and (c) rejected by classmates (reversed). The number of response options differed across the items; therefore, a scale score was created by first computing a z score for each item and then averaging across the three z scores.

Measures of Individual Characteristics and Cumulative Measures of Stress and Mobility

Gender. Gender data were taken from district records and coded as a dichotomous variable, with 0 = *female* and 1 = *male.*

Initial low income. Initial low-income status was assessed during the first 2 years of the project through parent surveys and was coded as a dichotomous variable with 0 = *not low income* and 1 = *low income.* Families who reported being eligible for free or reduced-price lunch program, Aid to Families with Dependent Children, or food stamps during Year 1 or Year 2 of data collection were coded as having initial low-income status.

Initial antisocial behavior. A five-item scale of antisocial behavior was drawn from teacher surveys administered in the fall when the children were in second or third grade. The scale consists of items taken from the TOCA–R (Werthamer-Larsson et al., 1990) and the Child Behavior Checklist (Achenbach, 1991). Items include: (a) argues a lot, (b) talks back to adults/is disrespectful, (c) lies, (d) stubborn, and (e) yells at others. Response options were: *rarely or never true*, *sometimes true*, and *often true*. A mean score was computed across items so that the scale had a range from 1 to 3. Correlations across Grades 2 through 5 ranged from .43 to .62 ($p < .001$).

Initial shy/withdrawn behavior. A five-item scale of shy/withdrawn behavior was drawn from teacher surveys administered in the fall when the children were in second or third grade. The scale consists of items taken from the TOCA–R (Werthamer-Larsson et al., 1990) and the Child Behavior Checklist (Achenbach, 1991). Items include: (a) shy or timid; (b) withdrawn, does not get involved with others; (c) avoids classmates; (d) likes to be alone; and (e) secretive, keeps things to self. Response options were: *rarely or never true*, *sometimes true*, and *often true*. A mean score was computed across items so that the scale had a range from 1 to 3. Correlations across Grades 2 through 5 ranged from .27 to .43 ($p < .001$).

Total school changes. A cumulative index of school changes was calculated by summing the total number of school changes a child experienced during the 4 study years. This measure included multiple school changes that some subjects made within one school year: Thirty-one students moved twice in 1 year and 2 students moved three times in 1 year. The most mobile students in the study experienced five school changes; thus, the variable ranged from 0 to 5.

Total family stress. A cumulative index of family stress was calculated by summing children's yearly experiences with family stress. Because four items were assessed during each of the 4 study years, students could have experienced a maximum of 16 stressors. The actual range for this sample was 0–13.

Analysis

Growth curve analyses were conducted using hierarchical linear modeling (HLM) 5.0 (Raudenbush, Bryk, Cheong, & Congdon, 2000). In the growth curve analysis framework, individual change is represented through a two-level hierarchical model in which the repeated measurements at Level 1 (e.g., yearly values on the outcome measures or covariates) are nested within individuals at Level 2 (e.g., person-level predictors such as gender and low-income status). In addition to the intercept and linear change parameters in the general Level 1 model, the time-varying covariates (yearly experiences with school transfers, teacher support, peer acceptance, and family stress) were specified at Level 1. Child characteristics (gender, initial low-income status, and initial antisocial and shy/withdrawn behavior) and cumulative variables (total number of school transfers and total number of family stressors) were included in the Level 2 equations.

Selecting the "center point" for time is a critical decision in the HLM process because it determines how one will interpret individual coefficients. Time in this study was coded (−3, −2, −1, 0) so that the interpretation of the intercept was at the last time point when the children were in fifth grade. The intercept was defined as the outcome at fifth grade because we were interested in examining specifically if school changes and other life circumstances altered the level of outcomes by the last time point in the study. Additionally, setting the intercept at the last time point ensured temporal ordering between the intercept and the cumulative school change and cumulative family stress variables.

Results

Analysis of the data proceeded in four phases. The first phase involved examining correlational data to consider the relationships among the variables prior to modeling growth in the outcome variables. In the next three phases of analyses, HLM models were built using a "step-up" strategy, starting by testing simple relationships and moving to more complex models with multiple variables (Raudenbush & Bryk, 2002). We selected a step-up strategy because in our initial analyses we tested models with all Level 1 and Level 2 predictors simultaneously and found that we did not have enough power to test these complex models.

Phase 1: Correlations

The matrix of correlations for child characteristics and across-time averages of each of the time-varying covariates and outcomes is provided in Table 2. Among the findings, the total number of school changes was positively associated with being low income at the beginning of the study and with receiving a higher teacher rating of antisocial behavior in the early years of data collection. School changes were also positively associated with the total number of stressful life events a child experienced during the study period. Finally, in terms of its relationship with the outcome measures, total school changes were correlated with academic performance and classroom participation but not with positive attitude toward school.

Another noteworthy finding was that, contrary to our hypothesis, teacher support was not correlated significantly with academic performance. Finally, across-time peer acceptance was found to be highly correlated with across-time classroom participation ($r = .67, p < .001$). Both of the measures were based on teacher ratings, and there was a concern that they were measuring the same construct. Therefore, peer acceptance was excluded in the models examining classroom participation and results do not appear in subsequent tables.

Phase 2: Fitting the Level 1 Models

A series of models for each of the three outcome variables examined the intercept (grand mean at fifth grade), the linear change (rate of growth), and slopes for each of the four time-varying predictors. Results of this phase of the analysis are shown in Table 3. First, an unconditional model containing the intercept and the linear change slope was estimated for each outcome (Table 3, column 1). The model provides a baseline measure of the intercept and average rate of growth on each outcome. Results indicate that each of the three outcomes was characterized by significant negative linear change.

***$p < .001$.

Next, the four time-varying predictors (yearly measures of school change, experience with family stress, teacher support, and peer acceptance) were added to the unconditional growth models one at a time to estimate the effects of children's exposure to these stressful and supportive conditions (Table 3, columns 2–5). The only exception, as mentioned earlier, was that the model testing the influence of peer acceptance on classroom participation was excluded due to high correlations. Each time-varying predictor was centered in a theoretically meaningful way to aid in the interpretation of the results. First, for yearly transfers and yearly stress, 0 represented the absence of a transfer or no experience with any of the four stressful family events. Second, the teacher support and peer acceptance predictors were "group-mean centered." Group, in this context, refers to the group of scores available for each child, and thus, within the analysis, the impact of teacher support and peer acceptance is in relationship to a student's own experiences over time not to that of his or her peers. Our choice to use group-mean centering stemmed from a concern that students who typically receive more support are the ones who do better in school. The correlation between across-time teacher support and across-time classroom participation ($r = .15$, $p < .001$) and positive attitude toward school ($r = .55$, $p < .001$) supports this relationship.

Results for the time-varying predictors indicate that peer acceptance and teacher support were significant and positively related to the prediction for two of the three tested outcomes (Table 3, columns 2–5). In addition, yearly transfers were significantly and negatively related to teacher ratings of academic performance. A child's yearly experience with stress was not a significant predictor for the growth trajectories of any of the three outcomes. Only the significant time-varying predictors were selected to move into the next phases of the model-building process.

A final step in this phase of the analysis involved testing cross-level interactions between the Level 2 child predictors and the slopes for time and each of the significant time-varying covariates. This step was undertaken to determine whether certain characteristics of the child were related to accelerations or decelerations in linear growth. To test these relationships, all Level 2 child predictors were tested on the slope of time and on the significant covariates for each outcome. Three significant or nearly significant cross-level interactions emerged from these tests and were included in subsequent tests to determine if they retained significance in the more complex models. These results are not shown in the tables. First, in the model testing the effect of teacher support on positive attitude toward school, the total number of school changes was significantly related to teacher support (coefficient = .055, $SE = .022$), $t(986) = 1.97$, $p < .021$. Second, for academic performance, two predictors approached significance: The total number of school changes slowed the growth of academic performance over time (coefficient = −.027, $SE = .013$), $t(986) = -2.34$, $p < .051$, and initial antisocial behavior predicted a reduction in the effect of peer acceptance on academic performance (coefficient = −.092, $SE = .046$), $t = -2.08$, $p < .056$.

Phase 3: Adding Level 2 Predictors and Significant Level 1 Covariates

This phase of analysis answered the first two research questions proposed for this study. The results are summarized for each outcome separately in Tables 4–6. The first question was, "Do experiences with elementary school mobility, measured cumulatively, diminish attitudes toward school and reduce the development of classroom participation and academic performance?" To answer this question, the total number of school changes a child made over 4 years was added to the intercept and linear change parameters within the unconditional growth model (Tables 4–6, column 1). Total school changes had a significant negative impact on fifth-grade classroom participation scores, $t(986) = -4.24$, $p < .001$, and scores for academic performance, $t(986) = -4.18$, $p < .001$, but was not significant for a child's positive attitude toward school. This is noteworthy because the experience of transferring schools was conceived as a risk factor, which might erode children's positive attitudes about school. These findings do not support this hypothesis. In terms of linear change, the total number of school transfers a child made significantly impacted the linear change over time for only one outcome: academic performance, $t(987) = -2.10$, $p < .05$. Because the number of transfers was significant in this step, it was retained as a predictor of the slope in subsequent models for academic performance. It was not retained as a predictor on the time slopes of the other two adjustment outcomes.

The second research question proposed in this study was, "Do risk factors, including gender, low-income status, antisocial and shy/withdrawn behavior, and overall family stress, play a role in explaining the relationship between mobility and school outcomes?" To answer this question, the remaining Level 2 child characteristics were included in the model on the intercept (Table 4–6, column 2). Results indicate that when the other five predictors are included in the

Table 4

*$p < .05$. **$p < .01$. ***$p < .001$.

models, the student mobility variable continues to have a significant negative effect on the intercept of classroom participation at fifth grade, $t(981) = -2.02$, $p < .05$, but not on academic performance. However, total transfers continue to significantly slow the linear growth of academic performance, $t(986) = -2.11$, $p < .05$.

Within these models, other child-level predictors did emerge as significant in predicting scores for the intercept at fifth grade. Initial antisocial behavior and low-income status contributed significantly to the intercepts of all three outcomes. Being male predicted declines in positive attitude toward school and classroom participation and having shy/withdrawn behavior predicted declines in classroom participation and academic performance. Finally, the total number of stressful family events a child experienced predicted declines in classroom participation.

Phase 4: Testing the Final Models

In the final stage of the analysis, each significant Level 1 covariate was entered one at a time to answer the third research question: "Do yearly measures of school change, family stress, peer acceptance, and teacher support impact the development of social and

academic outcomes, taking into account other risk factors?" Results of final models for each of the three outcomes are presented in Tables 4–6.

Classroom Participation

As shown in Table 4, column 3, teacher support had a positive and significant influence in the model, $t(981) = 5.65$, $p < .001$. Specifically, in years when children reported higher than average levels of teacher support, compared to their own scores across time, their classroom participation scores were estimated to improve. The total number of school changes retained significance, $t(981) = -2.03$, $p < .05$, even with the other five Level 2 predictors included in the model. Gender, initial antisocial behavior, and initial low-income status emerged as unique predictors of declines in children's classroom participation scores.

Positive Attitude Toward School

In the model testing the time-varying influence of teacher support (Table 5, column 3), teacher support was predictive of the growth trajectories for children's positive attitudes toward school, $t(986) = 22.13$, $p < .001$. In this model, gender and initial antisocial behavior were still significant predictors of positive attitude toward school, but low income was no longer a significant predictor.

The cross-level interaction between teacher support and the total number of school changes was also included in the analysis of attitude toward school (Table 5, column 3). Results indicate that the number of school changes a child experienced increased the strength of the relationship between teacher support and attitude toward school. In other words, teacher support is, in general, related to children's positive attitude toward school but is particularly important for those children who experience school changes.

The model including peer acceptance (Table 5, column 4) predicts a positive change in the growth trajectories for positive attitude toward school, $t(987) = 3.45$, $p < .001$. Of the child-level variables entered in the model, gender, initial antisocial behavior, and low-income status were significant predictors of fifth-grade positive attitude toward school.

Academic Performance

In the analysis of academic performance, results indicate that peer acceptance (Table 6, column 3) made a significant positive contribution, $t(986) = 10.23$, $p < .001$. In this model, three Level 2 predictors were statistically significant at $p < .001$ for academic outcomes at fifth grade: initial low-income status, antisocial behavior, and shy/withdrawn behavior.

Within the peer acceptance model, two cross-level interactions were significant. The interaction between peer acceptance and initial antisocial behavior was significant, $t(986) = -2.08$, $p < .05$, indicating that antisocial behavior decreases the effect of peer acceptance on academic performance. Additionally, the variable for total number of transfers, included on the time slope, was also significant, $t(986) = -2.34, p < .05$, indicating that the linear growth of academic performance was slowed by school transfers.

A second model, estimating the influence of yearly school changes on academic performance, was tested in a similar fashion (Table 6, column 4). In this model, yearly school changes predicted declines in the growth of academic performance, $t(987) = -3.02$, $p < .01$. Of the Level 2 child characteristics, three were significant at $p < .001$: initial low-income status, antisocial behavior, and shy/withdrawn behavior. Total number of transfers no longer predicted a change in the linear growth of academic performance.

Discussion

Research on mobility in schools has, until now, been limited by an inability to capture the complex conditions in which children make school changes. In this study, the application of growth curve analyses within a developmental science research framework allowed for the examination of school transfer effects within the context of other characteristics that may put children at risk for poor adjustment. Specifically, by including risk factors such as antisocial behavior, low-income status, and family stress, growth curve modeling enabled us to examine the unique effect of mobility. The analytic tools also allowed for the inclusion of temporal changes in students' transfer experiences and personal circumstances, opening up a dynamic view of mobility and related phenomenon. In this section, we highlight results for student mobility measures (both yearly and cumulative) and each of the time-varying predictors before proceeding with a discussion of limitations and implications.

Cumulative and Yearly Student Mobility Effects

The findings indicate that changing schools during the elementary school years predicts declines in classroom participation and academic performance, even when other potentially confounding predictors are included in the models. Results also show that the effect of changing schools operates a bit differently for each of these outcomes. For classroom participation, the total number of transfers a child made across the 4 years predicted lower levels of classroom participation at fifth grade. Changing schools does not, however, appear to have an immediate or year-to-year impact on classroom participation. These results are consistent with a number of mobility studies that showed that a single move may not impact children, but when moves accrue, their cumulative impact can be highly significant (Kerbow, 1996; Simpson & Fowler, 1994; Tucker et al., 1998; Wood et al., 1993). The findings for classroom participation are noteworthy, as research reporting a cumulative effect of mobility has focused on measures of academic achievement and behavior problems.

The effect of school transfers is robust and remains significant when other factors associated with school transfers are included in the equation. These factors—initial antisocial behavior, being male, initial low-income status, initial shy/withdrawn behavior, and total family stress—were also significant and appear to be strong predictors of classroom participation. Thus, the findings show that making a school change is only one of the significant factors that have a negative influence on the development of classroom participation.

The findings indicate that changing schools appears to have a different type of influence on the second significant outcome, academic performance, than it does on classroom participation. Annual and not cumulative mobility appears to affect teacher ratings of academic performance. During each school year, if a child changed schools at least once, the move or moves forecasted a decrease from the sample average slope for teacher-rated academic performance in the spring survey. Because we used a dichotomous measure, these results do not account for the multiple moves that 33 of the subjects made in a school year. We plan to examine the impact of these multiple moves in a future study.

The academic results reported here add evidence to the existing empirical literature on the association between annual school mobility and declines in academic achievement (Kerbow, 1996; Tucker et al., 1998). We were aware that a possible confounding variable might be that the children who move most often are simply the ones who would ordinarily show a decline in performance over time. However, in the final model run with the yearly transfer covariate, the total number of transfers was included on the slope. Thus, the effect was significant even when accounting for the performance of frequent movers.

We found no evidence that school changes, either the total number of transfers or the year-to-year measure of transfers, affected the growth trajectories of children's positive attitude toward school. This may be because school remains a positive influence for those who move, especially those who move often and experience other family stressors (Hetherington, 1979). The total number of transfers did play a minor but significant role in estimating the impact of teacher support on children's positive attitude toward school. Specifically, in the years that children in the sample felt significantly more teacher support than their average, their attitude scores were predicted to increase. In addition, this relationship between teacher support and attitude was stronger for children who moved more frequently. In other words, results suggest that the degree of teacher support is more important for the children who experience a school change. These findings are congruent with the research of DuBois et al. (1994), who found that young adolescents who experienced multiple economic disadvantages appeared to benefit more from social support received from adults in the school than do their "low-risk" peers.

Family Stress, Peer Acceptance, and Teacher Support Effects

In addition to examining the effects of student mobility, we considered alternative explanations for declines and increases in children's growth on the three outcomes. To this end, time-varying risk (yearly family stress) and protective factors (yearly measures of teacher support and peer acceptance) were added to hierarchical models to examine the relative explanatory strength of these factors. Of particular interest was the influence of family stress experiences because prior researchers have warned of a confounding effect of stress on school transfers. Contrary to expectations, a child's yearly experiences with family stress did not have a significant effect on any of the school engagement outcomes measured in this study.

One would expect that a child's exposure to the stress generated by divorce, job loss, or family death might result in at least temporary declines in school adjustment (DuBois et al., 1994). However, as the work of Hetherington (1979) shows, there is wide variability in the responses of children to divorce based on such factors as age, temperament, and changes in economic status. Further, not all family losses lead to greater conflict or strife within the family unit. In some cases, a parental breakup or death in the family may offer relief for children who have been living in a state of conflict or worry. Finally, a recent study by Gershoff, Aber, Raver, and Lennon (2007) suggests a much more complex relationship between family stress, low-income status, and child outcomes than the one examined in this study. Their work revealed that material hardship (i.e., months of financial troubles, food insecurity, inadequacy of medical care, residential instability) had a stronger association with family stress than income level. To more accurately assess the effect of stress, future studies of mobility should take into account these more nuanced measures of family stress and hardship.

In contrast to yearly family stress, the findings for both yearly protective factors were significant, providing evidence that social ties present in the school environment, or what some might call school social capital, serve to support successful outcomes. The findings lend support to the theory of appropriation (Vygotsky, 1962, 1978), which emphasizes that a child's adaptation to a learning environment is achieved by social means, through the people surrounding the child at school. First, yearly measures of a child's peer acceptance emerged as significant for both academic and attitudinal outcomes. In a given year, if peer acceptance was rated significantly above the child's average, his or her academic performance scores increased. One possible bias for this finding is that teacher ratings of academic performance at this age may be more a measure of how well children are getting along in class rather than a measure of achievement in math or reading. These findings should be interpreted with caution given the moderate correlation between teacher-rated peer acceptance and teacher-rated academic performance (r = .36). However, if replicated in future studies using other measures of academic growth, this finding would lend support to those who postulate that positive social interactions in the classroom facilitate intellectual development (Ladd et al., 1999).

Second, in the model testing the influence of peer acceptance on attitude toward school, positive attitudes were estimated to improve when children experienced above-average peer acceptance, though, when comparing their influence, teacher support appears to overshadow peer acceptance. These findings are consistent with developmental research showing that at this age, prior to the shift in adolescent social priorities toward peer relationships, teacher relationships are critical in terms of children's feelings about school (Birch & Ladd, 1997; Howes & Hamilton, 1993). One limitation of this study is that we did not collect data on children prior to their entry into school, during kindergarten, or during the transition to first grade. Research findings suggest that early school experiences, particularly relationships with teachers and peers, may have lasting effects on children (Birch & Ladd, 1997; Ladd et al., 1999; Pianta, Steinberg, & Rollins, 1995).

Results for the other protective factor indicate that children's perceptions of teacher support had a positive influence on the growth trajectories for children's classroom participation and positive attitudes toward school. Specifically, in a given year, when children indicated that they felt supported by their teachers significantly above their average, their classroom participation improved. In the same way, scores for positive attitude toward school improved during years when children reported more support, and, as mentioned earlier, mobile children received an additional boost in their positive feelings about school when they felt supported by teachers. The results here are not surprising given that the items we used to measure teacher support reflect a child's perspective on the condition of the relationship, emphasizing the level of helpfulness and caring present in the relationship (e.g., Does your teacher notice when you try hard? Do you like your teacher?). Prior research has established that children respond with improved attitudes and better behavior when they have closer relationships with their teacher (Birch & Ladd, 1997; Valenzuela, 1999; Wentzel, 1997). Contrary to expectation, the child's view of teacher support did not appear to impact teacher ratings of academic performance. Given that other researchers have found that warm and caring relationships with students influence academic outcomes, these results come as a surprise.

Implications for Practice in the Schools

Researchers have indicated that schools play a critical role in mitigating the negative effects of mobility on student outcomes and suggest that school personnel should be doing more to support students, given the high level of risk associated with school transfers (Mantzicopoulos & Knutson, 2000; Nelson et al., 1996; Vernberg, 1990). Unfortunately, a common concern raised by researchers is that few teachers have prior training in working with transfer students (Adelman & Taylor, 1991; Kerbow, 1996; Lash & Kirkpatrick, 1990). For example, Lash and Kirkpatrick (1990) found that teachers are trained to develop their instructional plans based on a classroom of students who will remain with them for an entire school cycle rather than assessing and teaching to the needs of students who enter in the middle of the year.

To improve outcomes for mobile students, a variety of practices have been suggested, including: intensive tutoring for high-risk transfers (Jason et al., 1992), careful assessment of social and academic strengths upon entry (Adelman & Taylor, 1991), facilitation of friendship formation and the acceptance of newcomers (Vernberg, 1990), and constructing a sense of stability and predictability in the school setting (Mantzicopoulos & Knutson, 2000). The intervention studies of high-risk elementary-age transfer students, conducted by Jason and colleagues in Chicago, have undergone the most systematic evaluation. In several controlled studies, transfer students participated in an orientation program and received biweekly tutoring with results indicating that the intervention improved student grades and achievement tests scores over the course of 1 year (Jason et al.; Jason et al., 1989, 1993). Despite including an orientation component, the intervention did not appear to positively influence social or behavioral outcomes for transfer students.

Taken together, the academic findings from the Jason studies and the behavioral and attitudinal findings of the present study hold some promise for practitioners hoping to mitigate the problems some students encounter following a school transfer. Results suggest that effective interventions for transfer students should include at least two components: (a) intensive tutoring to address the academic deficits of many transfer students and (b) university and school-based trainings to raise awareness of hardships encountered by mobile students, to increase caring responses, and to address peer acceptance in the classroom. Indeed, our previous research on school interventions indicates that a combined package of teacher, parent, and student training to support academic achievement and reduce problem behavior has impacted both school commitment and academic performance (Catalano et al., 2003).

Conclusions

One of the aims of this study was to use the developmental science framework (Magnusson & Cairns, 1996) to improve on prior research. This approach allowed us to build on the existing literature in a number of important ways. First, longitudinal data on elementary children have rarely been used in research on school mobility, especially data from studies that retained a large number of subjects. In the present investigation, all the analyses were calculated with a minimum of 94% of the original sample of preadolescent children. Even children who moved four or five times during the study years were retained in the analysis. Second, of the small group of published longitudinal studies on mobility, none have explored the relationship between school changes and classroom participation and positive attitude toward school. The findings presented in this study contribute to the existing research on the relationships between mobility, academic achievement, and behavior problems. Finally, this study demonstrated that growth curve modeling offers a powerful tool in the effort to understand how fluctuating circumstances can make a difference, both positively and negatively, for mobile children. Within the models examined in this study, a specific effort was made to shed light on changing relationships in the school that might protect children from undesirable outcomes associated with school changes.

Although the work presented here represents some key refinements in studying the developmental changes associated with mobility, a number of improvements must still be addressed. For example, within the developmental science framework, researchers are cautioned to be careful about the assumptions we make about stable factors. We chose to use a single measure of two child-level variables, antisocial behavior and low-income status, that emerged as significant predictors in most of the final models. Given their significance, future research that treats income status and antisocial behavior as time-varying factors might find that fluctuations in these variables significantly influence child outcomes. For example, a mobile child with a history of behavior problems could be influenced by a supportive teacher to make changes in classroom behavior leading to significant improvements in attitude or participation.

In outlining the developmental science framework, Magnusson and Cairns (1996) urge researchers to recognize the complexity of development and yet they acknowledge that "decisions must be made to bring some features to the foreground and move others into the background" (p. 8) in a given research project. In the present study, we used a predominantly Caucasian, suburban sample and chose to focus on protective relationships that might influence students in individual school settings. Clearly, these choices limit our ability to generalize to urban, more diverse, and more mobile populations. There is evidence in the literature that school-level effects, such as the pace of instruction and school climate, in urban schools with highly transient populations ought to be included in a longitudinal analysis of mobility (Alexander et al., 1996; Kerbow, 1996; Rumberger & Larson, 1998). Our choices also limited our ability to examine extrafamilial or neighborhood factors, including relationships with coaches, pastors, or caring neighbors who may support children new to neighborhoods and help them engage with school. Further, we did not examine the more traditional measures of social capital, including indicators of parent-community ties that may serve to support mobile students (Hagan et al., 1996; Pribesh & Downey, 1999).

In light of the limitations and strengths of this study, a promising direction for future research is to explore, using growth curve modeling, the changing family circumstances which may influence children's experience of moving. A study by Macmillan, McMorris, and Kruttschnitt (2004) marks a path in this direction by finding that the lives of young mothers and their children (ages 4–7) are bound together in significant ways. Among other things, the study shows that changes in maternal circumstances (e.g., meaningful escapes from or long-term movement into poverty) influenced children's antisocial behavior. The results are a clear invitation to include time-varying variables within the family context, such as fluctuations in family income and timing of divorce and remarriage, in future examinations of the consequences of mobility for children. Within the developmental science framework, growth curve modeling would allow for an examination of the theory (Lash & Kirkpatrick, 1990) that the reason why a family moves (e.g., upward mobility, forced mobility, lifestyle choice) leads to the great variation in consequences for children.

In a prospective study of developmental outcomes in relation to early-life otitis media, behavioral, cognitive, and language measures were administered to a large, diverse sample of children at 2, 3, 4, 6, and 9 – 11 years of age (N = 741). At 9 – 11 years of age, 9% of the children were categorized as having attention-deficit/hyperactivity disorder (ADHD) based on parent report. Compared to the non-ADHD group, the ADHD group had higher (i.e., less favorable) scores on parent and teacher versions of the Child Behavior Checklist at all ages. Children in the ADHD group also had lower scores on cognitive and receptive language measures in preschool. The findings support the concept that ADHD is a cognitive as well as a behavioral disorder.

The diagnosis of attention-deficit/hyperactivity disorder (ADHD) implies long-standing behavioral problems involving either inattention or hyperactivity – impulsivity or both (American Psychiatric Association, 1994). According to statistics from the 2003 National Health Interview Survey, the prevalence in that year of ADHD for U.S. children 3 – 17 years of age was 6% (Dey & Bloom, 2005), although a summary of epidemiologic studies in children 6 – 12 years of age reported a wider range of 4% – 12% (Brown et al., 2001). Overall, the prevalence of ADHD is at least 4 times higher in boys than in girls (Biederman et al., 2002; Gaub & Carlson, 1997). The wide reported range in prevalence may in part reflect the heterogeneity of the populations studied. Thus, the prevalence of ADHD is increased in certain populations, such as children born preterm (Bhutta, Cleves, Casey, Cradock, & Anand, 2002; Botting, Powls, Cooke, & Marlow, 1997) or who had low birth weights (Gray, Indurkhya, & McCormick, 2004; McCormick, Workman-Daniels, & Brooks-Gunn, 1996). Children of adolescent mothers are also at an increased risk of developing behavioral problems at school, hyperactivity, and learning disabilities (Camp, 1996). The prevalence of ADHD in children free of these biological and social risk factors has not been reported.

ADHD is associated with a wide range of functional impairments, including academic problems, educational underachievement, and peer social problems (Barkley, 2006; Weiss & Hechtman, 1993). The poor long-term school outcomes, including increased school absenteeism, grade retention, and dropout, of children with ADHD have been well documented in both population-based studies (Barbaresi, Katusic, Colligan, Weaver, & Jacobsen, 2007) and clinic-referred populations (for a review, see Loe & Feldman, 2007).

Typically, the diagnosis of ADHD is established when children are in elementary school. Several longitudinal studies have documented the persistence of behavioral characteristics of the disorder into adolescence and adulthood (Barkley, 2006; Biederman et al., 1998; Mannuzza, Klein, & Moulton, 2003). Many of the early longitudinal studies of children with ADHD focused mainly on boys from clinic-referred samples

who were recruited at school age (Mannuzza, Klein, Bonagura, & Konig, 1988; Weiss & Hechtman, 1993). Another limitation of the studies was the recruitment of matched controls at the time of follow-up rather than at the start of the prospective study. Despite these limitations, the consensus is that symptoms of ADHD persist after childhood. Approximately 65% of children with ADHD continue to meet diagnostic criteria for the condition as adolescents (August, Braswell, & Thuras, 1998; Ingram, Hechtman, & Morgenstern, 1999). Conversely, adolescents who are diagnosed with behavioral disorders commonly have a history of behavioral problems during the preschool years (Campbell, Shaw, & Gilliom, 2000; Loeber & Dishion, 1983).

Many cross-sectional studies rely on retrospective reports and have limited or no objective measures of behavior and cognition during the toddler and preschool years. In the absence of prospective, longitudinal studies, it is comparatively more difficult to learn about the early childhood behavioral or cognitive characteristics of children who are ultimately diagnosed with the disorder. Nonetheless, the developmental sequence of symptoms is important for understanding the origins of ADHD. If ADHD is primarily the result of a poor fit between active, exuberant children and demanding school environments, then children diagnosed at school age as having ADHD might have been indistinguishable from non-ADHD peers during their preschool years. In contrast, if the diagnosis of ADHD represents the culmination of long-standing behavioral and cognitive differences, then children diagnosed at school age as having ADHD should have had more behavioral problems and cognitive weaknesses than peers during their preschool years. If symptoms or precursors of ADHD can be identified during the early preschool years, such findings might help in the early identification of children with, or at risk for, the disorder and in turn might point to interventions aimed at improving long-term academic, educational, and social outcomes.

Several lines of evidence suggest that the behavioral characteristics of ADHD emerge during the preschool period. First, adolescents who are diagnosed with behavioral disorders commonly have a history of behavioral problems during the preschool period (Farrington, Loeber, & Van Kammen, 1990; Pardini, Obradovic, & Loeber, 2006). An obvious limitation of such research, however, is that the validity of the retrospective reports is inherently uncertain. Second, a cross-sectional study involving large samples of preschool, elementary, and secondary school children found teacher-reported symptoms of ADHD in 18.2% of the preschool children and slightly lower proportions among older children (Nolan, Gadow, & Sprafkin, 2001). Such prevalence data do not clarify whether the children with early symptoms would be the same ones who would later be diagnosed with ADHD.

Longitudinal studies that enrolled children as preschoolers also support the concept that symptoms of ADHD emerge in the preschool period. One such study recruited children who had been diagnosed with ADHD at 4–6 years of age from psychiatric clinics. These children tended to show persistence of the disorder as they entered school age (Lahey, Pelham, Loney, Lee, & Willcutt, 2005) though the subtype of ADHD sometimes shifted as children grew older; hyperactivity symptoms tended to decline from preschool to school age, whereas inattention symptoms remained stable. A limitation of such an approach is that it involved a clinical rather than a community sample. Children diagnosed at early ages may be among the most severely affected with the disorder, accounting for both the early age of identification and the continuity of symptoms. In a different experimental design, a longitudinal study of a small sample of twins discordant for attentional problems and ADHD at school age found that the twin with ADHD had more behavioral problems and attentional weaknesses as early as 2 years of age. However, the sample size of this study was small, and the circumstances of twinning are distinctive. Moreover, the affected twins also had delayed motor and slowed physical growth, suggesting that the affected child had more pervasive vulnerabilities (Lehn et al., 2007).

Campbell and colleagues conducted a longitudinal study of boys identified through flyers in preschool programs and pediatric offices, aimed at determining the continuity of symptoms of ADHD. The study followed "hard-to-manage" preschool boys and controls from ages 3 to 9 in the laboratory, home, and school settings (Campbell, Pierce, March, Ewing, & Szumowski, 1994; Campbell, Pierce, Moore, & Marakovitz, 1996; Campbell et al., 2000; Marakovitz & Campbell, 1998). The study excluded girls. Compared with control boys, at 4 and 6 years of age, the hard-to-manage group was more hyperactive, disruptive, irritable, and aggressive. By age 9, 36.5% of the hard-to-manage boys met the criteria for ADHD. Consistent with other studies, these results suggest that early onset of significant behavioral problems and hyperactivity is likely to be associated with persistence of those problems (Green, O'Reilly, Itchon, & Sigafoos, 2005; Sonuga-Barke, Auerbach, Campbell, Daley, & Thompson, 2005). Because the study was limited to boys with early behavioral symptoms, it is correspondingly limited in helping us understand the developmental course of children generally who are later identified as having ADHD.

Hyperactivity in preschool children is associated not only with later behavioral problems but also with mild intellectual impairment and poor preacademic skills (DuPaul, McGoey, Eckert, & VanBrakle, 2001; Sonuga-Barke et al., 2005). In the study cited previously, Marakovitz and Campbell (1998) reported that hard-to-manage boys also had significantly lower cognitive test scores at 4 and 6 years of age than the comparison group. A 12-year follow-up study of preschool children identified as "pervasively hyperactive" showed persistently poorer cognitive skills and lower levels of reading ability compared with their nonhyperactive peers (McGee, Partridge, Williams, & Silva, 1991). Correlations between externalizing behavioral problems and expressive language delays in toddlers also have been reported (Horwitz et al., 2003; Stevenson & Richman, 1978). However, the long-term outcomes of learning and academic skills in these children have yet to be elucidated.

The goal of the present study was to describe behavioral and cognitive antecedents of ADHD. This study improves on previously reported studies by considering a large and sociodemographically diverse community-based sample of boys and girls. In addition, the children were all full term, had normal birth weights, and were healthy at birth. Their mothers were all older than 18 years of age. Thus, the sample was at comparatively low risk for ADHD on the basis of these biological and social risk factors. The data were drawn from a large, longitudinal study of possible developmental consequences of early-life otitis media. The study participants had been followed prospectively from early infancy and had undergone developmental assessment at 2, 3, 4, 6, and 9–11 years of age, a longer time span than in several of the earlier studies cited previously. Results of this study have consistently shown that the duration of middle ear effusion (MEE) from otitis media, within the limits studied, is not associated with scores on a wide range of language, intellectual, academic, behavioral, and attentional measures at any of the ages tested (Paradise et al., 2000, 2003; Paradise et al., 2001; Paradise et al., 2005; Paradise et al., 2007). The present study compares the behavioral scores obtained at ages 2 to 9–11 years and the cognitive and receptive language scores obtained at ages 2–6 years, in children classified at 9–11 years of age as having ADHD, with corresponding scores in children in that age period classified as not having ADHD.

Method

Participants

The children in the present sample were enrolled in a prospective study that addressed possible developmental consequences of early-life otitis media (Paradise et al., 1997). A total of 6,350 infants less than 2 months of age were enrolled in the study at two urban hospitals, Children's Hospital of Pittsburgh and Mercy Hospital of Pittsburgh, and six nearby private pediatric group practices (two small town/rural and four suburban private practices) over a period of more than 4 years. The demographics of the sample resemble those of the greater Pittsburgh metropolitan area, consisting of primarily Caucasian and African American children and relatively few Hispanic, Asian, and no Native American children. The study's exclusion criteria ensured that the children were healthy at birth and at low risk for neurodevelopmental disorders. Infants who met any of the following criteria were excluded: birth weight less than 5 lb (2,268 g); small for gestational age; a history of neonatal asphyxia or other serious illness; a major congenital abnormality or chronic illness; multiple birth; a sibling enrolled in the study; in foster care or adopted; mother dead, seriously ill, a known drug or alcohol abuser, or, in the judgment of study personnel, too limited socially or intellectually to give informed consent or adhere to the study protocol; mother aged 18 years and younger; and English not the only household language. All children had parental consent to participate in the large study.

The study included two main components. One component was a randomized clinical trial in which children who met specified criteria regarding persistent MEE during the first 3 years of life were randomly assigned to have tympanostomy tubes inserted either promptly or up to 9 months later if MEE persisted. The other component consisted of a representative subgroup of enrolled children who ranged from those with no MEE to those with durations of effusion just short of meeting the study's criteria for randomization. These children were followed in the same fashion and underwent the same schedule of developmental assessments as the randomized children as described below. The study was approved by the institutional review boards of both participating hospitals (Paradise et al., 1997; Paradise et al., 2000; Paradise et al., 2001).

For the present study, we analyzed data from the 741 enrolled children who underwent developmental evaluation at 9–11 years of age. Figure 1 describes the subject selection for the current report. Larger proportions of children eligible for the randomized

clinical trial compared to those in the subgroup not eligible for randomization were Black, from urban areas, and from families of lower socioeconomic status (SES; based on maternal level of education and type of health insurance; Paradise et al., 1997). The children in the subgroup whose duration of otitis media with effusion did not reach the threshold for inclusion in the trial represented the range of MEE and SES of the original group of 6,350 children enrolled. The institutional review board of the University of Pittsburgh deemed the present analysis exempt from review.

Procedures

Parent interview. As a component of the visit when the children were 9–11 years old, study personnel interviewed parents about their children's health and neurodevelopmental status. Questions included (a) whether the child had any medical problems or had received any medical diagnoses, including neurobehavioral diagnoses such as ADHD; (b) whether any diagnoses not made were suspected; (c) whether the child was receiving stimulant medication or atomoxetine; (d) whether the child's parents or teacher had concerns about the child's learning abilities; and (e) whether the child was enrolled in special education or Title I reading or mathematics programs or was receiving after-school tutoring or any other school-based or private remedial service. We considered parents as valid informants of this information. Study personnel also collected demographic information, including the child's gender and race, place of residence, health insurance status, parents' educational attainment, and whether the parents lived in the home. Type of health insurance and maternal education were used as indicators of SES. Whether or not fathers were living in the home was used as a measure of environmental influence.

Criteria for classifying children. We classified children into the ADHD group if parents reported that (a) the child had been given the diagnosis of ADHD or (b) the diagnosis was suspected and the child was receiving a stimulant medication or atomoxetine. Only three parents reported that the children were suspected of having ADHD and were on medication. If parents reported either that (a) ADHD was suspected but that the child was not receiving medication or (b) ADHD was not suspected, the child was classified into the non-ADHD group.

Behavioral characteristics of participants at ages 9–11 years. We used the Child Behavior Checklist (CBCL) parent version (Achenbach, 1991a, 1992) and the CBCL teacher version or Teacher Report Form (Achenbach, 1991a) to assess behavioral characteristics of children at ages 9–11 years. These questionnaires ask informants to rate children on over 100 behavioral problems using a 3-point Likert scale, scoring statements as *not true, somewhat or sometimes true*, or *very or often true*. The results are presented as an age-adjusted *T* score (mean of 50 and standard deviation of 10) for the entire set (Total *T* score), externalizing (Delinquent Behavior, Aggressive Behavior) problems (Externalizing *T* score), and internalizing (Withdrawn, Somatic Complaints, Anxious/Depressed) problems (Internalizing *T* score). In addition, the questionnaire generates narrow-band *T* scores concerning eight different domains or subscales of behavior—Withdrawn, Somatic Complaints, Anxious/Depressed, Social Problems, Thought Problems, Attention Problems, Delinquent Behavior, and Aggressive Behavior. Higher *T* scores indicate larger numbers of behavioral problems and thus less favorable functioning. In the CBCL 4–18 versions used in this study, a Total Problems *T* score of 60–63 represented the 82nd–90th percentile for the normative sample studied; we chose this range as the borderline clinical range for the present analysis. However, the CBCL developers note that *T* scores from 60 to 63 are less clearly deviant than scores above 63 and highlight that cutoff points other than 60 may be more effective in particular samples (Achenbach, 1991b). A *T* score of 70 is considered clinically significant and represents the 97.7th percentile.

Classifying children into a learning problems group. We classified children as having learning problems if (a) the parent reported that either the parent or the teacher suspected a learning disorder and (b) the child was receiving any type of school-based, after-school, or private remedial support services. We accepted reports of any remedial educational service because the parents did not differentiate among special education services, Title I reading or mathematics support, academic accommodations, or other academic support services in their responses.

Early childhood measures. Table 1 summarizes the developmental assessments that had been performed when the children were 2, 3, 4, 6, and 9–11 years of age and that figure in the present analysis. All the children were tested individually within 2 months of their birthdays when their hearing was normal (unless they would not be able to be rescheduled within the required time frame) by trained personnel unaware of their medical history or SES. We used the CBCL parent version (Achenbach, 1991a, 1992) to assess behavioral characteristics of children each year from 2 to 6 and at 9–11 years of age and also the CBCL teacher version (Achenbach, 1991a) at 6 and 9–11 years of age.

To measure cognition when the children were 3 and 4 years of age, we used the McCarthy Scales of Children's Abilities General Cognitive Index (MSGCI; McCarthy, 1972). This test measures verbal, perceptual–performance, and quantitative skills and provides a composite score called the General Cognitive Index (GCI). Among the cognitive and intellectual measures available at the time of initiation of the study, we chose the McCarthy Scales of Children's Abilities because it was a well-respected and broad test of abilities that included verbal and nonverbal tests. The GCI has a mean of 100 and a standard deviation of 15, whereas the subtests have a mean of 50 and standard deviation of 10. To measure intelligence when the children were 6 years of age, we used the Wechsler Intelligence Scale for Children–Third Edition (WISC–III; Wechsler, 1991). The Full-Scale Intelligence Quotient (FSIQ), which has a mean of 100 and standard deviation of 15, integrates information from the verbal and performance scales. To assess receptive vocabulary at 3, 4, and 6 years of age as one aspect of language functioning, we used the Peabody Picture Vocabulary Test–Revised, Form M (PPVT–R; Dunn, 1981). The test has a mean of 100 and standard deviation of 15. Lower scores on all these measures indicate less favorable functioning.

Results

We used nondirectional tests for all analyses and set statistical significance at $p \leq .05$. There were 741 children included in the study. Of these, 69 children (9%) were classified into the ADHD group; within the ADHD group, 63 (91%) were being treated with stimulant medications or atomoxetine. Children who were only suspected of having ADHD but were not receiving medication were classified in the non-ADHD group; removing from the analysis data from these children does not substantively change the results.

Characteristics of Children According to ADHD Group

Table 2 summarizes selected demographic characteristics of the children we evaluated. We used

Table 1
Selected Assessments Performed at the Ages of 2, 3, 4, 6, and 9–11

		Age (years) at which assessment performed				
Domain	Test	2	3	4	6	9–11
Behavior	Child Behavior Checklist, parent version (2–3)	X	X			
	Child Behavior Checklist, parent version (4–18)			X	X	X
	Child Behavior Checklist, teacher version				X	X
Cognition	General Cognitive Index of McCarthy Scales of Children's Abilities		X	X		
Intelligence	Full-Scale Intelligence Quotient of Wechsler Intelligence Scale for Children–Third Edition				X	
Receptive vocabulary	Peabody Picture Vocabulary Test–Revised, Form M		X	X	X

Note. CHIP = Children's Health Insurance Program; ADHD = attention-deficit/hyperactivity disorder.

chi-square analyses to evaluate differences in proportions between the ADHD and the non-ADHD groups. Compared with the non-ADHD group, significantly larger proportions of children in the ADHD group were boys, $\chi^2(1) = 16.005$, $p < .001$; were enrolled in Medicaid insurance, $\chi^2(2) = 11.10$, $p = .004$ (excluding children with no health insurance or whose status was unknown); had parents with lower educational attainment; fathers, $\chi^2(2) = 14.2$, $p = .001$; trend for mothers, $\chi^2(2) = 5.6$, $p = .059$; and had fathers not living in the home, $\chi^2(1) = 5.3$, $p = .02$. Using a t statistic, we found that children in the ADHD group had a higher mean percent time with MEE during their first 3 years of life (M = 34.7%, SE = 1.61) than children in the non-ADHD group (M = 29.0%, SE = 0.75). This difference was significant $t(81.1) = 3.24$, $p = .002$, but was no longer significant after adjusting for child gender, type of health insurance, whether or not the father was living in the home, and level of maternal education, $F(1, 534) = 2.45$, $p = .118$.

Forty-seven of 69 children in the ADHD group (68%) also met criteria for having learning problems compared with 141 of 672 children in the non-ADHD group (21%), $\chi^2(1) = 73.4$, $p < .001$. Within each group, there were no significant interactions between any of the listed demographic variables and learning problems status.

Early Behavioral and Cognitive Measures in Children With and Without ADHD

Behavioral measures. We used repeated measures analysis of variance (ANOVA) to compare the two groups on developmental patterns of behavioral symptoms, as measured by parent CBCL ratings of children at ages 2, 3, 4, 6, and 9–11 years and teacher CBCL ratings of the children at ages 6 and 9–11 years. In these analyses, age was the within-subject variable and group (ADHD vs. non-ADHD) was the between-subject variable. Because sociodemographic variables were significantly related to group status, repeated measures analyses were conducted using specific sociodemographic variables (i.e., type of health insurance, level of maternal education, whether or not the father was living in the home) as covariates. Although paternal education also was significantly different between the groups, further examination revealed that for children whose fathers were not living in the home, data regarding paternal education were missing. Therefore, maternal education was used as the covariate.

Parent CBCL. Regarding the children's Total Problems *T* scores on the parent version of the CBCL at ages 2, 3, 4, 6, and 9–11 years, there was a main effect of group, with children in the ADHD group having consistently higher (i.e., less favorable) mean Total Problems *T* scores than children in the non-ADHD group, $F(1, 565) = 51.8$, $p < .001$. The difference between the groups was greatest at 9–11 years of age, when the ADHD group had a mean *T* score of 60.9 ± 11.1 compared with 47.1 ± 10.5 for the non-ADHD group. On repeated measures analysis, there was a significant main effect of time, $F(4, 562) = 6.36$, $p < .001$, and there was a significant Group × Time interaction, indicating divergence of the scores over time between the groups, $F(4, 562) = 11.3$, $p < .001$. Analysis of Externalizing *T* scores and Internalizing *T* scores showed similar patterns of results. After adjusting for type of health insurance, level of maternal education, and whether or not the father was living in the home, all differences between ADHD and non-ADHD groups remained as follows: (a) Total Problems *T* score: main effect of group, $F(1, 560) = 44.5$, $p < .001$, and of time, $F(4, 557) = 2.55$, $p = .039$, as well as Group × Time interaction, $F(4, 557) = 10.58$, $p < .001$; (b) Externalizing *T* score: main effect of group, $F(1, 559) = 42.56$, $p < .001$, and of time, $F(4, 556) = 4.21$, $p = .002$, as well as Group × Time interaction, $F(4, 556) = 6.32$, $p < .001$; and (c) Internalizing *T* score: main effect of group, $F(1, 560) = 18.16$, $p < .001$, and of time, $F(4, 557) = 5.24$, $p < .001$, as well as Group × Time interaction, $F(4, 557) = 4.42$, $p = .002$.

Repeated measures ANOVA was conducted to compare developmental patterns of behavioral symptoms, as measured by parent CBCL ratings of children at ages 2, 3, 4, 6, and 9–11 years using four groups: ADHD only, learning problems only, both ADHD and learning problems, and neither ADHD nor learning problems. Regarding the children's Total Problems *T* scores on the parent CBCL at ages 2, 3, 4, 6, and 9–11 years, the main effect of group remained, $F(3, 563) = 22.58$, $p < .001$. The significant main effect of time on repeated measures analysis also remained, $F(4, 560) = 6.97$, $p < .001$, and there was a significant Group × Time interaction, indicating divergence of scores over time, $F(12, 1{,}686) = 4.84$, $p < .001$. The results are summarized in Figure 2. Analysis of Externalizing *T* scores and Internalizing *T* scores showed similar patterns of results. After adjusting for covariates (type of health insurance, level of maternal education, and whether or not the father was living in the home), the differences remained as follows: (a) Total Problems *T* score: main effect of group, $F(3, 558) = 19.47$, $p < .001$, and of time, $F(4, 555) = 2.65$, $p = .033$, as well as Group × Time interaction, $F(12, 1671) = 4.46$, $p < .001$; (b) Externalizing *T* score: main effect of group, $F(3, 557) = 18.56$, $p < .001$, and of time, $F(4, 554) = 4.35$, $p = .002$, as well as Group × Time interaction, $F(12, 1668) = 2.87$, $p = .001$; and (c) Internalizing *T* score: main effect

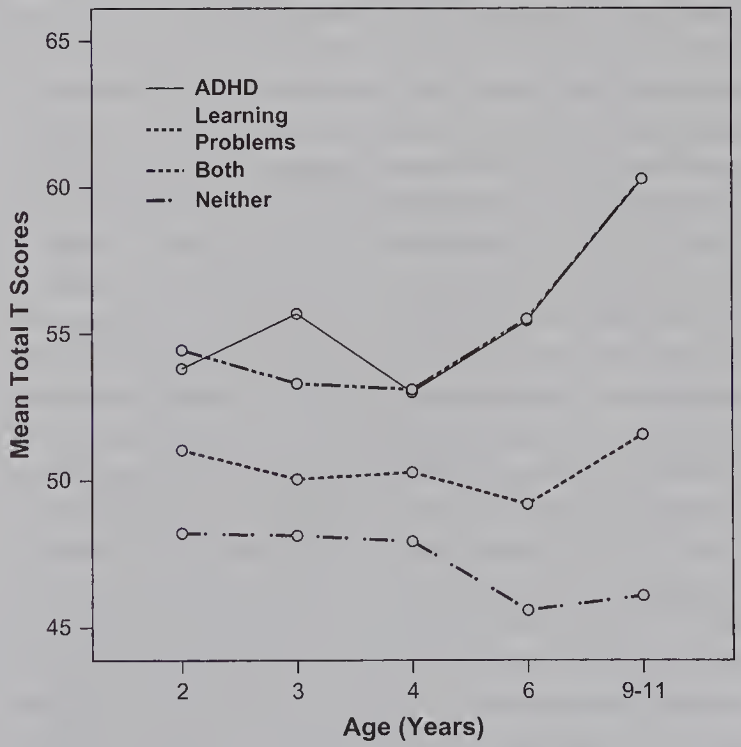

Figure 2. Mean Total Problems *T* scores on the Child Behavior Checklist, parent version, for children with ADHD only, learning problems only, both ADHD and learning problems, and neither ADHD nor learning problems at ages 2, 3, 4, 6, and 9–11 years. *Note.* ADHD = attention-deficit/hyperactivity disorder.

of group, $F(3, 558) = 12.31$, $p < .001$, and of time $F(4, 555) = 4.94$, $p = .001$, as well as Group × Time interaction, $F(12, 1671) = 4.65$, $p < .001$.

Teacher CBCL. Repeated measures ANOVA was conducted on data collected on the teacher CBCL regarding the children at ages 6 and 9–11 years. The results showed significant differences between the ADHD and the non-ADHD groups that remained significant after adjustment for type of health insurance, level of maternal education, and whether or not the father was living in the home. Compared with the non-ADHD group, the ADHD group had higher (less favorable) mean Total Problems *T* scores, $F(1, 630) = 58.83$; Externalizing *T* scores, $F(1, 630) = 30.02$; and Internalizing *T* scores, $F(1, 630) = 26.14$, all $ps < .001$. There were no significant main effects of time ($p > .05$). In addition to the main effect of group, there were significant Group × Time interactions for the Total Problems *T* score, $F(1, 630) = 4.95$, $p = .026$, and the Externalizing *T* score, $F(1, 630) = 9.48$, $p = .002$, but not for the Internalizing *T* score, $F(1, 630) = 0.25$, $p = .615$.

Repeated measures ANOVA was also conducted to compare developmental patterns of behavioral symptoms, as measured by teacher CBCL ratings of children at ages 6 and 9–11 years, again using four groups: ADHD only, learning problems only, both ADHD and learning problems, and neither ADHD nor learning problems. Regarding the children's Total Problems *T* scores on the teacher CBCL, the main effect of group remained, $F(3, 633) = 59.73$, $p < .001$. As in the two-group analysis, there was no significant main effect of time, $F(1, 633) = 2.43$, $p = .120$. In addition, there was a trend suggesting Group × Time interaction, $F(3, 633) = 2.61$, $p = .051$. Analysis of Externalizing *T* scores and Internalizing *T* scores revealed similar results. After adjusting for type of health insurance, level of maternal education, and whether or not the father was living in the home, the differences remained as follows: (a) Total Problems *T* score: main effect of group, $F(3, 628) = 52.26$, $p < .001$, no effect of time, $F(1, 628) = 0.33$, $p = .567$, as well as a trend for Group × Time interaction, $F(3, 628) = 2.57$, $p = .053$; (b) Externalizing *T* score: main effect of group, $F(3, 628) = 22.62$, $p < .001$, no effect of time, $F(1, 628) = 1.97$, $p = .161$, as well as Group × Time interaction, $F(3, 628) = 4.76$, $p = .003$; and (c) Internalizing *T* score: main effect of group, $F(3, 628) = 24.82$, $p < .001$, no effect of time, $F(1, 628) = 0.64$, $p = .424$, and a lesser trend for Group × Time interaction, $F(3, 628) = 2.26$, $p = .081$. Figure 3 summarizes the children's Total Problems *T* scores on the teacher CBCL for the four groups at ages 6 and 9–11 years. Possible interactions between ADHD and learning problems groups were investigated using multivariate ANOVA (MANOVA) and are discussed in the Results section.

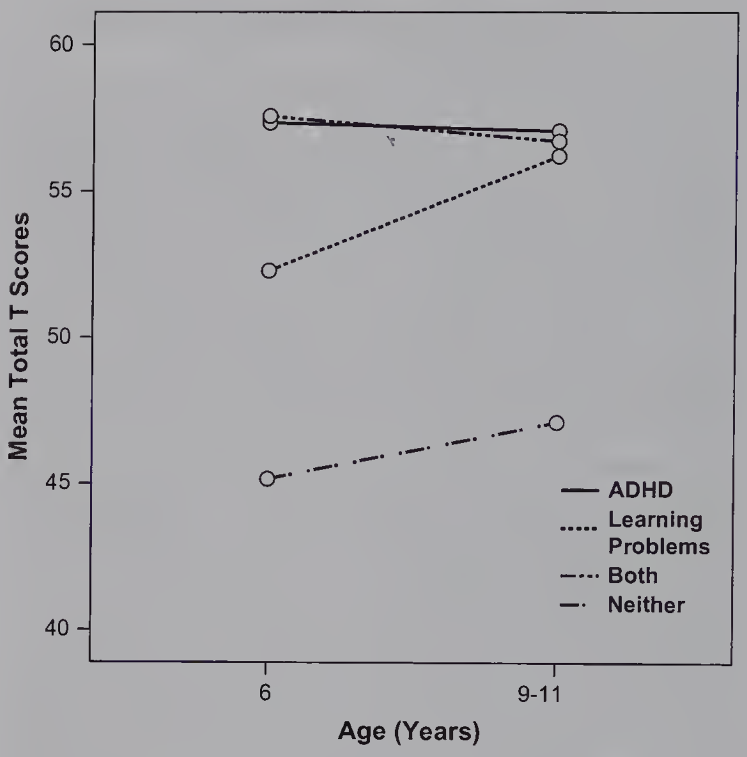

Figure 3. Mean Total Problems *T* scores on the Child Behavior Checklist, teacher version, for the children with ADHD only, learning problems only, both ADHD and learning problems, and neither ADHD nor learning problems at ages 6 and 9–11 years. *Note.* ADHD = attention-deficit/hyperactivity disorder.

Narrow-band scores on the parent and teacher CBCLs. Narrow-band scores on subscales of the parent CBCL were evaluated at ages 4, 6, and 9–11 years using the Mann–Whitney test. A nonparametric test was chosen because the *T* scores on the subscales did not follow a normal distribution. Data from ages 2 and 3 years were not analyzed because a different version of the CBCL with different subscales was used at those ages. Parent CBCL *T* scores at age 4 years were significantly higher among children with ADHD than among children without ADHD on all subscales (all $ps < .05$) except Somatic Complaints and Anxious/Depressed. At age 6 years, parent CBCL *T* scores were significantly higher among children with ADHD on all subscales (all $ps < .05$) except Somatic Complaints. Teacher CBCL *T* scores at that age were significantly higher among children with ADHD on all subscales (all $ps < .05$).

On the parent CBCL, at ages 9–11 years, children in the ADHD group had significantly higher *T* scores than children without ADHD on all eight subscales, including Attention Problems, ADHD $Mdn = 65$ versus non-ADHD $Mdn = 50$, $U = 5{,}903$, $z = -10.76$; Aggressive Behavior, ADHD $Mdn = 58$ versus non-ADHD $Mdn = 50$, $U = 10{,}453$, $z = -8.59$; and Delinquent Behavior, ADHD $Mdn = 62$ versus non-ADHD *Mdn* = 50, *U* = 11,638, *z* = −7.36, all *ps* < .001. On the teacher CBCL at ages 9–11 years, *T* scores on all subscales were also significantly higher among children with ADHD than without ADHD (all *ps* < .005).

Cognitive and receptive language measures. Figure 4 shows the mean standard scores for the ADHD and non-ADHD groups on the MSGCI at ages 3 and 4 years. At both ages, scores were lower (i.e., less favorable) in the ADHD group (at age 3, ADHD *M* = 92.03 ± 11.83 vs. non-ADHD *M* = 103.64 ± 12.81; at age 4, ADHD *M* = 86.35 ± 12.62 vs. non-ADHD *M* = 102.04 ± 13.75). Mean scores on the WISC–III at age 6 years were also lower in the ADHD group (88.98 ± 14.82 vs. 101.58 ± 14.01). Using repeated measures ANOVA, there was a main effect of group, $F(1, 641) = 66.83$, $p < .001$; this difference remained significant after adjusting for the same sociodemographic variables as those used in prior analyses, $F(1, 636) = 54.39$, $p < .001$. A significant Group × Time interaction also was found, $F(2, 640) = 6.74$, $p = .001$: From ages 3 to 4 years, mean standard scores on the MSGCI in children with ADHD showed a greater decrease than in children without ADHD.

Figure 5 shows the children's mean standard scores on the PPVT–R at ages 3, 4, and 6 years. Scores again were lower in children in the ADHD group than in the non-ADHD group. The main effect of group remained significant after adjusting for the same sociodemographic variables as those used in prior analyses, $F(1, 644) = 22.21$, $p < .001$. There was no significant Group × Time interaction, $F(2, 643) = 1.01$, $p = .366$.

Note. ADHD = attention-deficit/hyperactivity disorder.

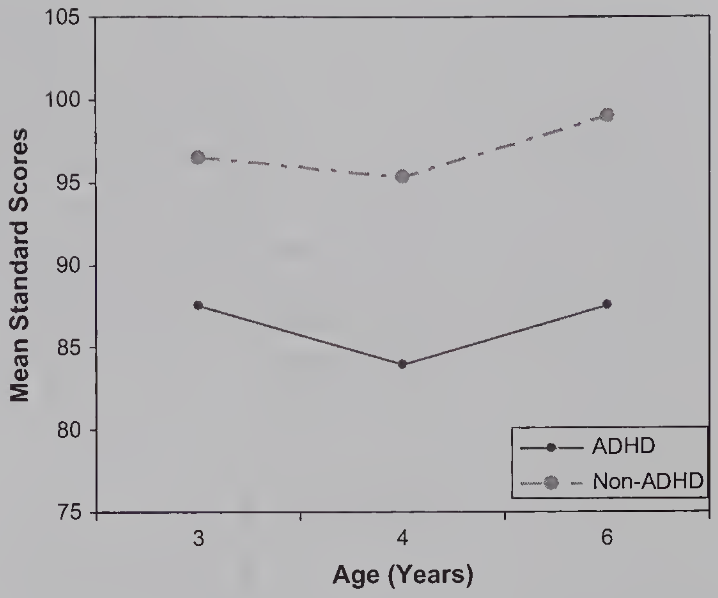

Figure 5. Mean standard scores on the Peabody Picture Vocabulary Test–Revised in the children in the ADHD and non-ADHD groups at ages 3, 4, and 6 years.
Note. ADHD = attention-deficit/hyperactivity disorder.

Impact of Learning Problem Status on Early Behavioral and Cognitive Measures in Children With and Without ADHD

Impact on early behavioral measures. Table 3 shows mean scores on the early childhood behavioral measures with the ADHD and non-ADHD groups divided into subgroups with and without learning problems. For the behavioral measures, a MANOVA was conducted using ADHD status and learning problems status as independent variables; type of health insurance, level of maternal education, and whether or not father was living in the home as covariates; and Total Problems *T* scores on the parent CBCL at 2, 3, 4, 6, and 9–11 years of age as the dependent variables. Results showed significantly higher (less favorable) Total Problems *T* scores in the ADHD group (with or without learning problems) at all ages, $F(4, 554) = 12.24$, $p < .001$, than in the learning problems group (with or without ADHD), $F(5, 554) = 1.45$, $p = .206$. There was no interaction between ADHD group and learning problems group, $F(5, 554) = 0.86$, $p = .511$.

Similar MANOVAs of teacher CBCL Total Problems *T* scores at ages 6 and 9–11 years showed a different pattern of results. Children with ADHD had higher scores than children without ADHD (regardless of learning problems status), $F(2, 627) = 18.54$, $p < .001$. Children with learning problems had higher scores than children than children without learning problems, $F(2, 627) = 5.81$, $p = .003$, and there was also a significant ADHD Group × Learning Problems Group interaction, $F(2, 627) = 5.75$, $p = .003$. These analyses included as covariates the same sociodemographic variables as those used in prior analyses.

Table 3

Behavioral and Cognitive Test Scores in Children Classified as ADHD With or Without Learning Problems

	ADHD											
	No						Yes					
	No learning problems (n = 531, 72%)			Learning problems (n = 141, 19%)			No learning problems (n = 22, 3%)			Learning problems (n = 47, 6%)		
Measures	*M*	*SD*	*n*	*M*	*SD*	*n*	*M*	*SD*	*n*	*M*	*SD*	*n*
Parent CBCL (Total *T* scores)[a]												
Age 2 years	48.1	9.2	467	51.3	9.6	123	53.8	10.0	21	54.8	11.3	43
Age 3 years	47.9	9.5	480	50.1	8.8	115	56.2	6.6	20	54.0	11.7	43
Age 4 years	48.0	9.6	470	50.4	9.2	122	53.3	11.2	21	53.4	12.3	42

Ages 9–11 years	46.0	10.0	410	51.7	11.2	99	61.0	9.3	19	60.8	11.9	39
Teacher CBCL (Total *T* scores)[a]												
Age 6 years	45.0	10.0	462	52.7	10.6	122	58.8	7.6	20	58.8	8.8	42
Ages 9–11 years	46.9	10.4	456	56.5	9.4	120	58.0	11.0	19	57.7	7.0	42
Cognition/intelligence/receptive language[b]												
MSGCI at age 3 years	105.1	12.8	490	95.9	11.3	121	97.8	11.5	20	89.3	11.1	42
MSGCI at age 4 years	104.0	13.1	490	92.7	12.9	125	94.9	8.3	21	82.4	12.5	44
WISC–III FSIQ	104.0	13.0	486	90.8	13.1	124	101.0	10.6	21	83.7	12.9	44
PPVT–R at age 3 years	98.0	15.4	496	89.1	12.3	122	93.2	8.4	20	84.6	15.0	41
PPVT–R at age 4 years	97.4	15.8	491	86.8	15.2	125	92.4	13.0	21	79.0	14.2	44
PPVT–R at age 6 years	101.0	14.7	484	88.9	13.4	125	94.9	11.4	21	83.5	14.5	44

Note. ADHD = attention-deficit/hyperactivity disorder; CBCL = Child Behavior Checklist; MSGCI = McCarthy Scales of Children's Abilities General Cognitive Index; WISC–III FSIQ = Wechsler Intelligence Scale for Children, Third Edition, Full-Scale Intelligence Quotient; PPVT–R = Peabody Picture Vocabulary Test–Revised, Form M.
[a] Higher scores reflect less favorable results. [b] Lower scores reflect less favorable results.

To probe these findings further using planned comparisons, an independent samples *t* test was conducted to compare Total Problems *T* scores on the parent CBCL at ages 2, 3, 4, and 6 years in the subgroups of children within the ADHD and non-ADHD groups who had and did not have learning problems. Using a Bonferroni correction because of multiple comparisons, significance was set at $p < .01$. In children with ADHD, the behavioral scores did not differ at age 2 years between the learning problems subgroup ($M = 54.77$, $SE = 1.73$) and the non-learning-problems subgroup ($M = 53.81$, $SE = 2.18$), $t(62) = -0.329$, $p = .743$, or at any of the later ages (all *p*s $> .05$). However, in children without ADHD, the behavioral scores did differ at age 2 years. Thus, non-ADHD children with learning problems had significantly higher Total Problems *T* scores ($M = 51.20$, $SE = 0.86$) than did non-ADHD children without learning problems ($M = 48.15$, $SE = 0.428$), $t(588) = 3.24$, $p = .001$. Non-ADHD children with learning problems also had significantly higher Total Problems *T* scores at age 6 than those without learning problems ($p < .001$).

Impact on early cognitive and receptive language measures. Similar analyses were conducted to assess the combined impact of ADHD status and learning problems status on cognitive and receptive language measures. For cognitive measures, a MANOVA was conducted using ADHD status and learning problems status as the independent variables; type of health insurance, level of maternal education, and whether or not the father was living in the home as covariates; and mean standard scores on the MSGCI at ages 3 and 4 years and on the WISC–III FSIQ scores at age 6 years as the dependent variables. At all ages, cognitive scores were significantly lower (less favorable) in the ADHD group compared to the non-ADHD group (regardless of learning problem status), $F(3, 632) = 8.00$, $p < .001$. Cognitive scores were also significantly lower at all ages in the learning problems group than in the non-learning-problems group (regardless of ADHD status), $F(3, 632) = 23.01$, $p < .001$. There was no interaction between ADHD group and learning problems group, $F(3, 632) = 1.34$, $p > .05$.

Regarding the receptive language measures, a MANOVA was conducted in which ADHD status and learning problems status were the independent variables; type of health insurance, level of maternal education, and whether or not the father was living in the home were covariates; and mean standard scores on the PPVT–M at ages 3, 4, and 6 years were the dependent variables. Mean scores at all ages were significantly lower in children with learning problems than in those without learning problems, $F(3, 640) = 14.34$, $p < .001$, but there were no significant differences in mean scores between children with ADHD and those without ADHD, $F(3, 640) = 1.43$, $p > .05$. There was no interaction between learning problems group status and ADHD group status, $F(3, 640) = 1.60$, $p > .05$. On both the cognitive and the receptive language measures, mean scores in children with both ADHD and learning problems were approximately 1 *SD* or more below the mean scores in children with neither ADHD nor learning problems.

Discussion

Main Findings

This study compared children 9–11 years of age with and without ADHD with regard to their behavioral, cognitive, and receptive language scores at 2, 3, 4, and 6 years of age and their behavioral scores at 9–11 years of age. Children in the ADHD group had consistently less favorable mean scores not only on behavioral ratings but also on cognitive and receptive language measures than did children in the non-ADHD group. Behavioral problem ratings in the ADHD group increased over time, whereas in the non-ADHD group, they decreased.

Prevalence of ADHD

The longitudinal study from which the present data are derived followed participants who were free at birth of many biological and social risk factors associated with ADHD. Despite those exclusion criteria, 9% of the sample had ADHD either reported or suspected and treated with medication. This value is within the range of 4%–12% reported in epidemiologic studies that do not exclude children with such risk factors (Brown et al., 2001) but higher than might be expected in a low-risk sample. Some of these children might not have met strict diagnostic criteria for ADHD, but the differences between groups on so many measures confirm that the two groups were substantially different from one another.

Prevalence of Learning Problems

Learning problems are highly prevalent in children diagnosed with ADHD. In our study, we classified children into the learning problems group on the basis of a parent's or a teacher's suspicion of a learning problem coupled with a child's receipt of any kind of remedial service. This liberal definition resulted in 68% of the children with ADHD having learning problems compared with 21% in the non-ADHD group. The reported rates of co-occurrence of learning disorders and ADHD vary across studies due to the lack of standardized definitions for learning disorders. The National Center for Health Statistics reported that in 1997 – 1998, 4% of U.S. children aged 6 – 11 years had both attention-deficit disorder and learning disability (Pastor & Reuben, 2002). Their definition of a specific learning disability comes from the Individuals With Disabilities Education Act, Section 300.541, and requires a discrepancy between intelligence and academic achievement (Individuals With Disabilities Education Improvement Act of 2004). This definition identifies fewer children than do other definitions. Other studies have reported the co-occurrence of ADHD and learning disorders to range from 11% (Wolraich, Hannah, Baumgaertel, & Feurer, 1998) to 70% (Mayes, Calhoun, & Crowell, 2000). Our results were similar to those of other studies that find substantial correlations between learning problems and ADHD (DuPaul & Stoner, 2003; Loe & Feldman, 2007) and, in particular, to the results reported by Biederman et al. (1998) who found that 84% of children with ADHD required extra help in school.

Characteristics of Children in the ADHD Group

We found that ADHD was associated with demographic and socioeconomic factors. As in other studies (Biederman et al., 2002; Gaub & Carlson, 1997), we found that larger proportions of children in the ADHD group were boys. Compared with children in the non-ADHD group, children with ADHD were also more likely to be enrolled in Medicaid insurance, to have parents with lower educational attainment, and to have fathers not living in the home. We considered type of health insurance and level of maternal education as indicators of SES, and whether the father was living in the home as an important demographic characteristic. The impact of SES on the diagnosis of childhood ADHD varies across studies. Although low family income and poverty status have been associated with lower probability of diagnosis (Bussing, Zima, Gary, & Garvan, 2003), a population-based cohort study found inverse associations of maternal and paternal education levels with risk for ADHD (St Sauver et al., 2004). A large, cross-sectional British epidemiologic survey found no independent association between ADHD diagnosis and either socioeconomic or family characteristics, including marital status and single-parent home (Ford, Goodman, & Meltzer, 2004). However, a study using a longitudinal cohort in the United States found that children with an ADHD diagnosis were less likely to be living with a biological father (Schneider & Eisenberg, 2006). The duration of MEE in this study differed between the ADHD and the non-ADHD groups; however, this difference did not persist after adjusting for demographic variables, presumably because the adverse demographic factors associated with ADHD are also important demographic risk factors for MEE.

Behavioral Measures

A major finding of this study was that the mean CBCL Total Problems *T* scores for children in the ADHD group were elevated in comparison to the children in the non-ADHD group as early as age 2 years. In addition, the Total Problems *T* scores increased (i.e., became less favorable) over the period between age 4 and 9 – 11 years, whereas the *T* scores for children in the non-ADHD group decreased during that period. Results were similar regarding the Internalizing and Externalizing *T* scores. Other studies of children developing typically report reductions over time in preschool behavioral problems such as aggression (Cummings, Ianotti, & Zahn-Waxler, 1989; Smith, Calkins, Keane, Anastopoulos, & Shelton, 2004). Our results show that children with ADHD were distinguishable from those without ADHD as toddlers and that the differences between the two groups become progressively more pronounced until at least school age.

Relations Between Behavioral Measures and Learning Problem Status

Another notable finding of this study was the increase in teacher ratings of behavioral problems in children in the learning problems group (without ADHD) from age 6 to 9 – 11 years. Parent reports showed that children in the learning problems group without ADHD had higher scores than children with neither ADHD nor learning problems. However, there was no Age × Group interaction. Teacher scores for the learning problems group at age 6 years were lower than those for children with ADHD with or without learning problems. However, the teacher scores became similar to those of children with ADHD with or without learning problems from age 6 to 9 – 11 years. This finding suggests that the number of behavioral problems in the children with learning problems and without a diagnosis of ADHD increases more in the school setting than in the home environment over time. Behavioral problems in this group of children may increase because of their struggles to meet the academic demands of the school.

Cognitive and Receptive Language Measures

Importantly, the findings of this study are consistent with the concept that ADHD is a cognitive as well as a behavioral disorder. The ADHD group had lower (less favorable) scores than the non-ADHD group on the MSGCI at ages 3 and 4 years and on the WISC – III FSIQ at age 6 years. These findings are consistent with those of other studies (Faraone et al., 1993; Marakovitz & Campbell, 1998). Children in the ADHD group also had lower mean scores on the PPVT – R, a test of receptive vocabulary, which correlates with verbal intelligence.

Similarly, children in the learning problems group had significantly lower cognitive and receptive vocabulary scores than children in the non-learning-problems group. The children with both ADHD and learning problems at school age had lower cognitive and receptive vocabulary scores at 3, 4, and 6 years of age than did children who had either one or none of the conditions. The differences were at least 1 *SD* in magnitude.

Limitations and Considerations for Future Studies

The estimates of ADHD prevalence in this study were based on parent reports of the diagnosis of ADHD or the use of relevant medication at ages 9–11 years. The prevalence of learning problems was based on a parent or teacher suspicion of learning problems and the receipt of remedial services of many different types. Future studies would ideally include more detailed diagnostic information using an ADHD-specific questionnaire or rating scale and a standardized diagnostic interview for ADHD and comorbid conditions. More detailed information from neuropsychological and/or psychoeducational testing could improve categorization of children's specific learning problems. Information on educational services (i.e., setting, provider, content, length, intensity) gathered by a structured services assessment measure such as the Services for Children and Adolescents – Parent Interview (Jensen et al., 2004) would also improve the ability to characterize remedial support for children's learning problems. Another limitation is the lack of information regarding family history of ADHD. Parent symptoms of ADHD are likely to affect parent – child interactions as well as how the parent views the child's behavior.

The exclusion criteria of the study from which the present sample was derived resulted in the exclusion of children at heightened risk for ADHD on the basis of low birth weight, prematurity, parental substance use, and mothers less than 18 years of age. The findings from our study may therefore not be generalizable to higher risk samples. In addition, the sample included relatively few Hispanic, Asian, and middle-class Black infants and no Native American infants (Paradise et al., 1997). Finally, parents who declined to enroll their infants tended to have higher SES than parents who enrolled their infants, and enrolled infants from lower SES families were more likely to have been lost to follow-up and to have incomplete data sets. On the other hand, upper- and lower-middle-class, working-class, and indigent families were all represented in substantial numbers (Paradise et al., 1997).

Developmental Implications and Conclusions

Research on the characteristics of children with ADHD during early childhood has been limited. This study provides support for the concept that ADHD is a chronic condition associated with adverse behavioral and cognitive characteristics in the toddler and preschool period. That the development of children with ADHD differs from children without ADHD at very young ages suggests that the disorder is not simply the result of poor adaptation to school environments. Behavioral and cognitive problems that are manifest in the preschool years in children who are ultimately diagnosed with ADHD in the middle school years appear to be relatively stable traits. Whereas in children who do not have ADHD, behavioral scores decrease (improve) over time, our data indicate that behavioral symptoms in children with ADHD tend to worsen by middle childhood, as rated by both parents and teachers.

In children with ADHD, the presence or absence of a learning problem did not appear to influence how parents or teachers viewed the level of behavioral problems. In contrast, in children with learning problems alone and not diagnosed with ADHD, teachers' perceptions of behavioral problems were much higher than parents' perceptions. This perception of increased behavioral problems at school age in the children with learning problems suggests that difficulty with academic work and poor adaptation to school are associated with deteriorating behavior over time.

Future longitudinal studies should attempt to determine whether early intervention for children at risk for ADHD can improve their long-term outcomes. In addition, the identification of other precursors of ADHD during the toddler and early preschool years may help enable the early identification of children with, or at risk for, ADHD and in turn might suggest interventions for improving their long-term academic, educational, and social outcomes.

Postural and Object-Oriented Experiences Advance Early Reaching, Object Exploration, and Means – End Behavior

Michele A. Lobo and James C. Galloway
The University of Delaware

The effects of 3 weeks of social (control), postural, or object-oriented experiences on 9- to 21-week-old infants' (N = 42) reaching, exploration, and means – end behaviors were assessed. Coders recorded object contacts, mouthing, fingering, attention, and affect from video. Postural and object-oriented experiences advanced reaching, haptic exploration of objects, and developing means – end behavior compared to social experience. Object-oriented experience best-advanced means – end behavior. The results suggest that the development of novel behaviors is dependent on multiple subsystems and can be similarly advanced by addressing a variety of these subsystems. They also suggest that past experiences with active object exploration can facilitate early information processing and the development of early knowledge.

Early experiences shape the development of many skills in infancy, such as early stepping (Vereijken & Thelen, 1997; Zelazo, Zelazo, Cohen, & Zelazo, 1993), reaching (Lobo, Galloway, & Savelsbergh, 2004), object exploration (Needham, Barrett, & Peterman, 2002), and crawling (Adolph, Vereijken, & Denny, 1998). The goal of this project was to assess the effects of advanced parent – infant experiences on the future development of three behaviors proposed to be developmentally related: (a) reaching, (b) object exploration, and (c) means – end behavior. We predicted that altering parent – infant interactions when infants were 2 – 3 months of age and not yet reaching would propel infants onto different developmental trajectories in the months after the prescribed experiences ended. In the current study, parents provided just 3 weeks of advanced postural or object-oriented experiences. We assessed the effects of these experiences on future reaching, object exploration, and means – end behavior across a 12-week period.

The onset of the ability to reach at about 4 months of age is a milestone that alters daily life for infants and their parents (E. J. Gibson, 1988; Thelen et al., 1993; von Hofsten, 1991). Prior to the onset of reaching, infants in the United States spend most of their time supine on their backs engaging in face-to-face social interactions (Davis, Moon, Sachs, & Ottolini, 1998; Fogel, Messinger, Dickson, & Hsu, 1999; Mildred, Beard, Dallwitz, & Unwin, 1995). If parents introduce objects to their infants in these months, they typically present them to infants out of reach for visual inspection (Eppler, 1995; Fogel, 1997; Fogel et al., 1999). Parents occasionally place objects in infants' hands or mouths; however, the grasping ability required for sustained oral or manual object exploration does not emerge until after the onset of reaching (Konczak & Dichgans, 1997; Rochat, 1989). Infants move their arms often in the period before they begin to reach with and without the presence of objects or people. It is through these spontaneous movements that infants explore the biomechanics of their bodies and the forces acting upon them and gain the motor control required for later object interaction (Bhat, Heathcock, & Galloway, 2005; Thelen, 1990; von Hofsten, 1993). In effect, the period before the onset of reaching could be termed a primarily "supine, spontaneous, and social period."

After reaching emerges, infants' and parents' daily activities change. Infants move their arms with more control, which allows for more purposeful interaction with objects (Bhat et al., 2005; Thelen et al., 1993). The onset of reaching also coincides with the time when infants typically begin to assume more varied postural orientations, rolling prone and supine, being

---

This study was conducted as the doctoral thesis for M.A.L. and was funded by dissertation fellowships through The University of Delaware. We thank the families who generously agreed to participate in this study, our wonderful undergraduate research assistants, especially Rachel Farley, Rebecca Silver, Lindsey Moore, Morgan Randles, and Lauren Emerson, for hours of coding assistance and the members of the thesis committee, Nancy Getchell, Slobodon Jaric, and Mark Stanton, for their invaluable input throughout the project.

Correspondence concerning this article should be addressed to Michele A. Lobo, Motor Behavior Laboratory, Department of Physical Therapy, 329 McKinly Lab Building, The University of Delaware, Newark, DE 19716. Electronic mail may be sent to malobo@udel.edu.

placed vertical and in semireclined sitting more often, and sitting with assistance (Fogel et al., 1999; Snow, 1989). Better postural control coupled with reaching and grasping ability allows infants to independently explore objects in new ways for sustained periods through mouthing and touching (Adolph, Eppler, Marin, & Wechsler-Clearfield, 2000; J. J. Gibson, 1979). Furthermore, the onset of reaching changes the parent–infant–object dynamic. As parents observe their infants' emerging ability to interact with objects, they begin to present repeated, daily opportunities for their infants to haptically interact with objects (Fogel, 1997; Fogel et al., 1999; Reed & Bril, 1996). Compared to the prereaching period, the period following the onset of reaching could be termed a primarily "postures, purpose, and play period."

In our previous work, we showed that advanced general movement experiences and object-oriented experiences advanced infants' abilities to reach for objects (Heathcock, Lobo, & Galloway, 2008; Lobo et al., 2004). Below we detail why we chose to expand on these results by assessing the effects of advanced postural and object-oriented experiences on not only reaching but also on later object exploration and means–end behavior.

The Role of Postural Experiences in the Ontogeny of Reaching

The first objective of this project was to test whether advancing the development of postural stability would advance the onset of reaching. Postural stability involves the ability to dynamically maintain the position of the body, or the center of mass, within one's stability limits (Shumway-Cook & Woollacott, 1995). The role of parents in promoting the development of postural stability in early infancy has been documented in several cross-cultural (Bril & Sabatier, 1986; Hopkins & Westra, 1988, 1989, 1990) as well as prospective (Davis et al., 1998; Hadders-Algra, Brogren, & Forssberg, 1996) studies. Young infants lack the mobility to independently transition between positions, thus the variety of positions and postural challenges they experience is largely a function of how parents handle them. Therefore, the emergence of postural stability is dependent not only upon the evolving abilities of infants but also upon parents' responses to these abilities.

Postural stability has been proposed as a requirement for reaching (Bertenthal & von Hofsten, 1998; Hopkins & Ronnqvist, 2002; Rochat & Goubet, 1995; Savelsbergh & van der Kamp, 1993). Developmentally, postural advancements accompanied improvements in reaching (Fallang, Saugstad, & Hadders-Algra, 2000; Fontaine & le Bonniec, 1988; Rochat, 1992; Spencer & Thelen, 2000). Reaching also improved in real time when external postural stability was provided (Amiel-Tison, 1985; Grenier, 1981; Rochat & Goubet, 1995). If postural stability facilitates reaching, then advancing the development of postural stability should advance the emergence of reaching (Bertenthal & von Hofsten, 1998; Hopkins & Ronnqvist, 2002; Rochat & Goubet, 1995). Being placed more often in postures, such as sitting and standing, has been shown to directly advance the emergence and control of these postures (Bril & Sabatier, 1986; Hopkins & Westra, 1988, 1989, 1990; Zelazo et al., 1993). This is the first study to attempt to assess the effects of advanced postural stability on another unpracticed behavior (reaching). The postural experiences prescribed in this project were non-object-oriented experiences aimed at advancing postural stability across a variety of positions. We hypothesized that infants who received enhanced postural experience would have advanced reaching emergence and ability compared to control infants.

The Role of Object-Oriented Experiences in the Ontogeny of Reaching

The second objective of this project was to test whether providing earlier than typical object experience would advance reaching. Parents play an important role in helping their infants learn to reach around 4–5 months of age by presenting them with objects to reach for and scaffolding their early reaching attempts (Fogel, 1997; Fogel et al., 1999; Reed & Bril, 1996). Young infants cannot independently seek out objects; thus, they rely on parents to present them with opportunities to interact with objects. Therefore, as with postural stability, the emergence of reaching is dependent on the evolving abilities of infants as well as parents' responses to these evolving abilities (Bakeman, Adamson, Konner, & Barr, 1990; Bruner, 1972; Landry & Chapieski, 1988).

Experience moving and interacting with objects has been proposed to be an important factor in the emergence of reaching (Bhat & Galloway, 2006; Fogel et al., 1999; Thelen et al., 1993). Specifically, reaching was advanced after 2 weeks of daily, object-oriented movement experiences provided 1–2 months prior to typical reach onset (Lobo et al., 2004). If experience haptically interacting with objects facilitates reaching, then advancing parent–infant interactions to incorporate objects earlier should again advance the emergence of reaching (Fogel, 1997; Fogel et al., 1999; Lobo et al., 2004; Reed & Bril, 1996). Here, we assessed the effects on reaching behavior across a longer time span. The object-oriented experiences prescribed in this project were aimed at advancing infants' reaching ability and haptic experience with objects in supine. We hypothesized that infants who received enhanced object experience would have advanced reaching emergence and ability compared to control infants.

The Role of Reaching Experience in the Ontogeny of Object Exploration

The third objective of this project was to test for a developmental connection between reaching and object exploration. That is, would infants in groups who reached early due to the effects of enhanced postural or object-oriented experiences also display advanced object exploration? Infants learn to extract information about the affordances and properties of objects through active object interaction (Campos et al., 2000; E. J. Gibson, 1988; J. J. Gibson, 1979). Not surprisingly, the emergences of reaching and object exploration are important milestones linked with abilities across multiple domains, including cognitive, social, and language (Bremner, 2000; E. J. Gibson, 1988, 2000; Needham, 2000; Piaget, 1952, 1954). The onset of reaching is rapidly followed by the ability to grasp objects for sustained periods (Wimmers, Savelsbergh, Beek, & Hopkins, 1998; Wimmers, Savelsbergh, van der Kamp, & Hartelman, 1998). This grasping ability coupled with increased opportunities to explore objects presented by parents may be important in transitioning infants into more frequent, purposeful, exploratory object interactions.

Although experience actively exploring objects has been viewed as necessary for infants to learn about the actions they can perform on objects (Bourgeois, Khawar, Neal, & Lockman, 2005; Case-Smith, Bigsby, & Clutter, 1998; Needham, Cantlon, & Holley, 2006), for infants less than 6 months of age, we know of only one study assessing reaching and exploration behaviors in combination (Needham et al., 2002). In that study, nonreaching infants given experience interacting with objects using sticky mittens with Velcro later showed greater object engagement and haptic exploration of objects. If experience actively exploring objects facilitates early knowledge about how to examine objects, then advancing the onset of reaching should advance object exploration behavior. This project aimed to determine the effect of advanced reach onset on the ontogeny of object exploration. We hypothesized that infants in groups expected to reach earlier (postural and object experience) would show more haptic exploration of objects earlier compared to control infants.

The Role of Object Experience in the Ontogeny of Means–End Behavior

The final objective of this project was to test for a connection between reaching, object exploration, and means–end behavior. That is, would infants who had been reaching and exploring objects longer also display advanced means–end behavior? By acting on objects, infants learn information about the match between their actions and external events (E. J. Gibson, 2000). For instance, by exploring a jack-in-the-box, infants learn that cranking the handle results in the sight and sounds of a toy. Such active interaction with objects has been proposed to be the vehicle by which infants gain knowledge about more complex action–environment relationships such as means–end relationships (Bremner, 2000; E. J. Gibson & Pick, 2000; Piaget, 1952, 1954; von Helmholtz, 1962). Means–end behavior involves acting on one object as the means to affect another object (Munakata, Bauer, Stackhouse, Landgraf, & Huddleston, 2002). Most means–end studies test infants older than 6 months of age with the general consensus that means–end behavior is present by 8 months of age (Funk, 2002; Lewis, Alessandri, & Sullivan, 1990; Munakata et al., 2002).

Several studies have investigated the emergence of means–end knowledge (Funk, 2002; Gowen, Goldman, Johnson-Martin, & Hussey, 1989; Menard, 2005). Visual attention paradigms have suggested that infants may possess means–end knowledge before they can demonstrate means–end behavior (Hofstadter & Reznick, 1996; Sommerville & Woodward, 2005b). It remains unclear how to reconcile the discrepancies between the behavioral and visual studies. One account for the discrepancies is the means–end deficit account, which claims that young infants may possess means–end knowledge but cannot demonstrate it because they cannot perform the tasks typically used to measure means–end behavior (Shinskey & Munakata, 2001).

To study the early emergence of means–end behavior, we designed a task in which the means were in line with infants' skills and the end was meaningful to young infants. The requirements of the means–end tasks used in other studies are too difficult for infants younger than 6 months of age (Hood, 2001; Menard, 2005). For example, infants younger than 6 months are not able to grasp and pull a towel or to grasp and lift an enclosure while reaching for and grasping an object behind the enclosure with the opposite hand (Bojczyk & Corbetta, 2004; Corbetta, Thelen, & Johnson, 2000; Fagard, 2000). Similar to studies with older infants, our means–end task required that infants coordinate their existing behaviors to perform in an unfamiliar task, acting on one object to affect another while demonstrating intention via interest in the "end" object (Munakata et al., 2002; Willatts, 1999). However, our task required motor, perceptual, and affect regulation abilities that young infants possess. If experience acting on objects facilitates the learning of means – end relationships, then advancing the onset of reaching and object exploration should advance emerging means – end behavior. We hypothesized that infants who had the longest duration of active object exploration, those who received object-oriented experiences prior to the onset of reaching, would show the most advanced means – end behavior.

Method

Participants

Healthy, full-term infants entered the study when they were 8 – 11 weeks of age and not yet reaching. Before Visit 1, 42 infants were randomly assigned to the social experience (control) group (age at Visit 1: M = 61 days, SD = 5 days, range = 54 – 77 days), the postural movement experience group (age at Visit 1: M = 62 days, SD = 5 days, range = 57 – 79 days), or the object-oriented movement experience group (age at Visit 1: M = 61 days, SD = 5 days, range = 55 – 74 days). Infants among groups were matched for gender. Each group contained 7 boys and 7 girls. We located families with infants through local birth announcements. Parents provided informed consent. All infants were from two-parent families. Two infants were African Americans, and the remaining infants were Caucasians.

Fourteen additional infants were excluded from the sample. Nine were excluded because of advanced reaching at Visit 1 evidenced by more than 10 object contacts during the reaching task. Excluding these infants was important because one objective of this study was to determine the effect of advanced experiences on the initial emergence and subsequent development of reaching. The remaining 5 infants were excluded because of parents' inability to provide home experience for more than 60% of the days during the 3-week prescribed home experience period. We requested that parents provide the experiences daily yet emphasized that missing occasional days would be an acceptable reality. Parents reported in journals how much experience was provided daily and were unaware of the 60% criterion. Please see the Results section for specifics on parental reports of provision of experiences. Participants received certificates of participation and DVD recordings of their infants' first and fifth visits as gifts upon completion of the study.

Procedure

The same experimenter visited families in their homes for six visits over a period of 12 weeks. Visits 1, 3, 4, 5, and 6 were separated by 3 weeks. Visits 1, 2, and 3 were separated by 1.5 weeks. We documented each session using two synchronized video recordings to provide right- and left-side views of infants for coding. A splitter was used to place both views on one screen, and a vertical interval time code generator was used to superimpose the hour, minute, second, and frame on the image.

Parents provided enhanced experiences daily only between Visits 1 and 3. Thus, parents were asked to provide the experiences for a total of 3 weeks when infants were between 2 and 3 months old. At each visit, we assessed infants' ratings on the Alberta Infant Motor Scale (AIMS) and performance in three tasks: (a) use of arm movements to reach, (b) use of arm movements to explore objects, and (c) use of arm movements to explore a means – end task.

Rating on the AIMS

At each visit, we observed infants' general motor development and rated them using the AIMS (Piper & Darrah, 1994; Piper, Pinnell, Darrah, Maguire, & Byrne, 1992). AIMS scores were used to ensure that the three groups were not different in their motor development at the initiation of the study and as an independent measure of whether the activities provided to the postural experience group actually resulted in advanced postural development. The AIMS is a valid and reliable developmental assessment tool that compares infants' motor performance to that of a normative sample to provide percentile rankings reflecting general motor development. It consists of observation of infants' weight bearing, posture, and antigravity movement in supine, prone, sitting with support, and standing with support.

Task 1: Using Arm Movements to Reach

At each visit, infants were provided opportunities to reach for an object while lying supine and sitting upright in a custom seat (Figure 1). In the seat, infants had their trunks secured but had freedom of movement of their arms. In each position, an object was held stationary in midline at the infant's chest level for six 30-s trials. The object distance was determined at the

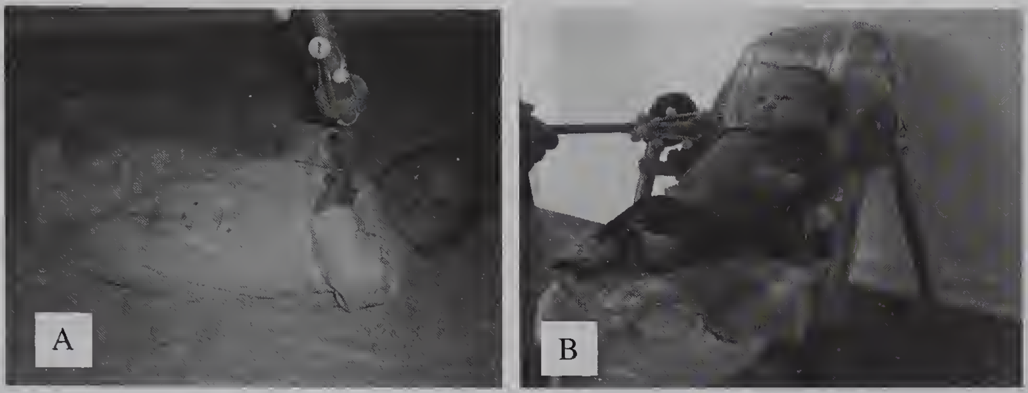

Figure 1. Task 1: One infant positioned supine (A) and vertically in the seat (B) for the assessment of the use of arm movements to reach.

beginning of each session by extending the infant's arm into midline, noting the location of the infant's wrist, and presenting the object in this location. Trials began when infants were in a positive behavioral state and visually attending to the object (Prechtl, 1974).

Task 2: Using Arm Movements to Explore Objects

At each visit, infants were provided opportunities to use arm and hand movements to haptically explore objects while sitting upright in our seat. Infants could not reliably grasp objects for prolonged periods at the start of the study. Thus, objects were attached to infants' wrists using Velcro bands (Figure 2). The experimental design for this task was based on Ruff (1984). Three pairs of objects varying in weight, texture, or sound-making ability were presented to infants for exploration. One object in each pair served as the familiarization object, and the other object served as the novel object. Infants had 60 s to explore each familiarization object and 45 s to explore each novel object. These times kept the familiarization period longer and novelty period shorter similar to Ruff. But the total presentation time for each pair (familiarization period plus novelty period) was shorter to increase the likelihood that the very young infants in this study could complete the entire paradigm. For the purposes of this article, we focus on global exploration of the objects by grouping the data.

At each visit, the familiarization and novelty trials were immediately preceded by the experimenter attaching the object to the wristband, raising the hand and object into the infant's view, and then releasing the hand at the start of the trial. There was no contact between the experimenter and infant during trials. Successive objects were attached to alternating hands. The initial hand of attachment was the right for half of the infants in each group and left for the others. Within infants, the initial hand of attachment was altered at each visit.

Task 3: Using Arm Movements to Explore a Means–End Task

At each visit, infants were provided opportunities to use arm movements to explore a means–end relationship while sitting upright in our seat (Figure 3). The means–end task began with a 30-s pre-means–end period followed by two means–end periods. During the pre-means–end period, a toy was placed to the left of the infant at a distance of 1 m (see C in Figure 3). The toy was within view but out of reach of the infant and was inactive. This period allowed us to

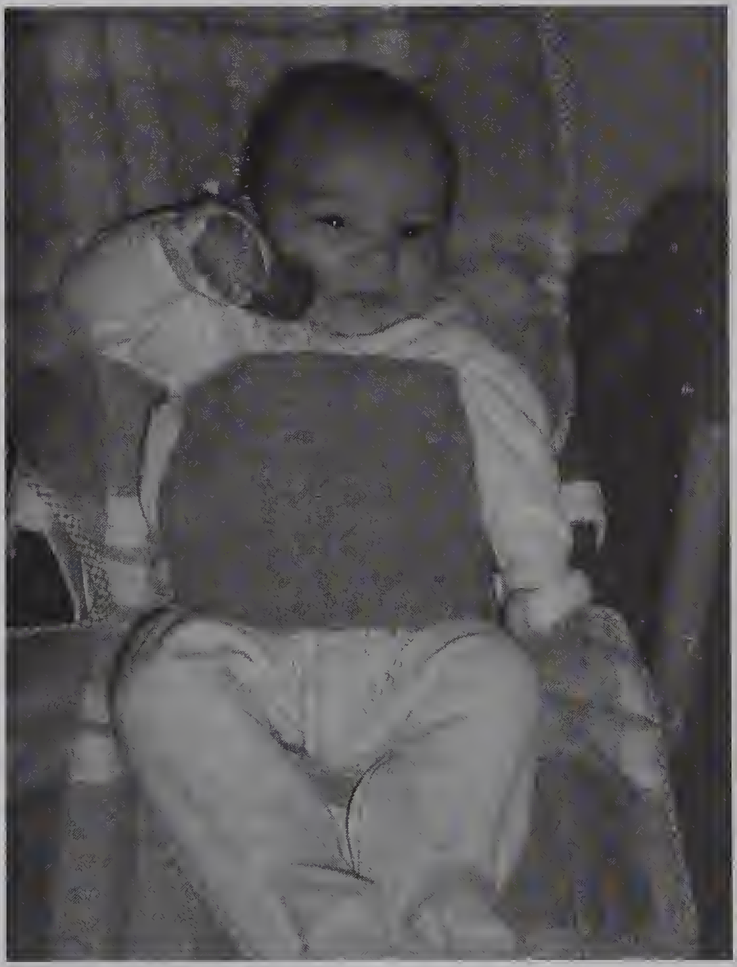

Figure 2. Task 2: One infant positioned in the seat for the assessment of the use of arm movements to explore objects.

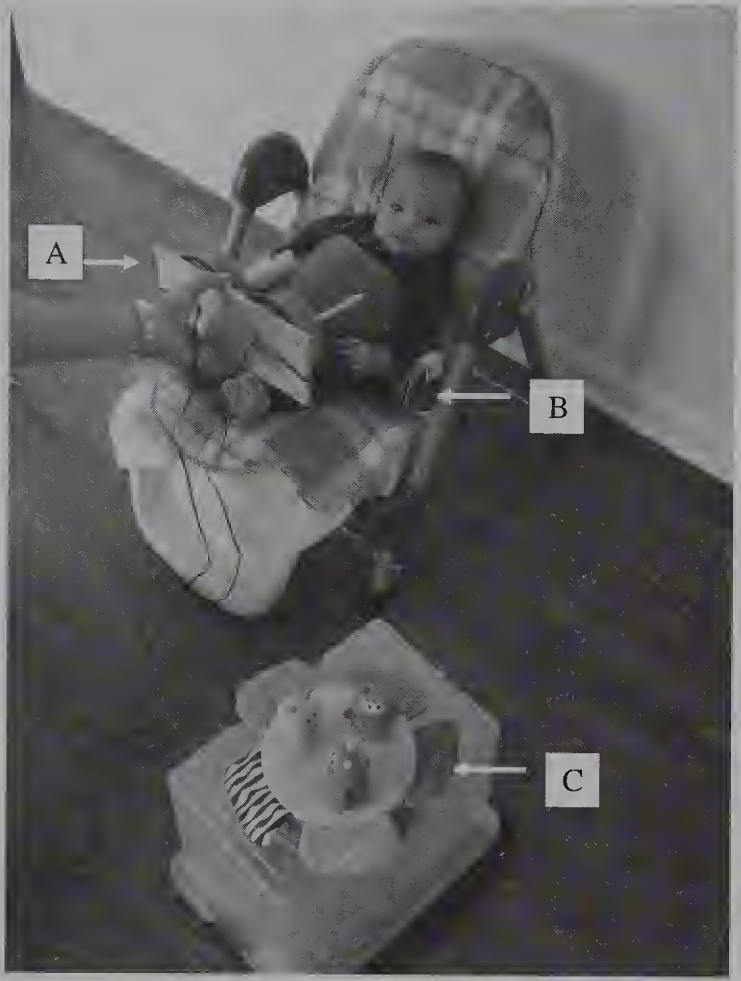

Figure 3. Task 3: One infant positioned in the seat for the assessment of the use of arm movements to explore a means – end task. *Note.* Note the two lever switches in the infant's reach (A), the small light secured to the chair (B; out of the infant's view), and the musical spinning bug toy (C; out of reach, in view for the infant).

test for changes in visual attention to the toy when it was not active or under infants' control.

The assessment continued with two means – end periods, one 4-min period followed by a second 3- to 4-min period. The length of the second period was dependent on the behavioral state of the infant (Prechtl, 1974). During both periods, the toy remained in its position and two lever switches were presented to infants within reach, one laterally to the right and one to the left (see A in Figure 3). To test infants' knowledge of the means – end relationship, switch – toy control was altered so one switch activated the toy during the first means – end period and the other switch activated the toy during the second means – end period. The position of the switch activating the toy during the first means – end period was counterbalanced among subjects in each group.

The lever switches were activated immediately when infants reached to displace them in any direction. One switch activated the toy ("toy activations"), which resulted in colorful plastic bugs spinning in circles to music. The other switch activated a light attached to the seat ("nonactivations"; see B in Figure 3). The light allowed coding of nonactivations and was out of the infant's view.

A certain level of activity was required for infants to demonstrate means – end behavior. Therefore, in the early visits, we discontinued the assessment if infants produced five or less total activations of the switches within the first 2 min of the first means – end period. When an infant met this criterion, the entire assessment was completed for that visit and all subsequent visits.

Prescribed Home Experiences

Parents in each group were asked to perform the home experiences for 15 min daily throughout the first 3 weeks of the study (Visit 1 to Visit 3) in addition to their typical daily activities. After Visit 3, parents were informed that they did not need to continue performing the home experiences for the purposes of this project. Although this amount of experience seems minimal, we have seen large changes in behavior as a result of prescribed experiences of similar durations (Lobo et al., 2004). It is likely that these changes result from carryover of the prescribed activities into daily parent – child interactions.

Parents were taught to provide the experiences via demonstrations from the experimenter at Visit 1 along with illustrated instruction manuals kept by parents. At Visit 2, parents were asked to perform an independent demonstration of the experiences with their infants for the experimenter and to discuss any questions or concerns regarding the experiences. Parents tracked the frequency and duration of their performance of the experiences in daily journals.

Social experience. Parents in the social experience group were asked to position their infants in supine while encouraging face-to-face, non-object-oriented interaction for 15 min. This served as a control for the increased social interaction and associated general movement that infants in the postural and object experience groups would receive.

Postural experience. Parents in the postural experience group were asked to perform non-object-oriented activities to improve postural stability and midline hand movement ability for 15 min. Specifically, the activities involved parents assisting infants to push up in prone, to pull up supine to sitting, to maintain their heads and upper trunks upright when their lower body was moved different directions in supported sitting and standing, and to move their hands to midline for clapping play.

Object-oriented experience. Parents in the object-oriented experience group were asked to teach their infants to reach for midline objects and to encourage haptic exploration of objects. To teach reaching, parents spent 5 min for each hand showing the infant his or her hand, showing an object at midline, moving the hand to the object, and then allowing the infant opportunities to perform this actively. To encourage haptic exploration of objects, parents spent 5 min assisting infants to feel objects varying in characteristics such as shape, size, texture, and hardness with their hands and mouths.

Data Analysis

Arm movement task coders were blind to group assignment. AIMS coding was performed by a pediatric physical therapist. Coding reliability was assessed based on a comparison of agreements and disagreements from each visit. For each variable, the number of behaviors coders agreed and disagreed on was determined and percentage of reliability was calculated using the equation: $[\text{agreed}/(\text{agreed} + \text{disagreed})] \times 100$. This is a strict measure of reliability (Angulo-Kinzler & Horn, 2001; Harris & Lahey, 1978; Lobo et al., 2004). Individuals were qualified for coding once they achieved and maintained inter- and intrarater reliabilities greater than 90%.

Variables for Rating on the AIMS

Changes in AIMS ratings across the span of the home experience (Visit 1 to Visit 3) and across the span of the study (Visit 1 to Visit 6) were analyzed in total and for the supine, prone, sitting, and standing subscales.

Variables for Task 1: Using Arm Movements to Reach

The variables for this assessment were analyzed in total with secondary analyses for the supine and vertical positions because previous research suggested that early vertical reaching abilities are more advanced than supine (Carvalho, Tudella, & Savelsbergh, 2007; Savelsbergh & van der Kamp, 1994).

Numbers of infants reaching. An infant was categorized as reaching if he or she contacted the object more than five times in 3 min of supine or vertical object interaction. These criteria are based on our past reaching studies (Lobo et al., 2004) with infants demonstrating that infants who have learned to reach perform this action repeatedly and reliably across all sessions after the onset of reaching with high numbers of object contacts.

Numbers and durations of object contacts. Object contact occurred when any surface of the hand contacted the object. Right- and left-limb variables were summed, such that, for example, one bilateral contact was counted as two contacts. Duration of each contact was coded using the time code on the video.

Numbers of infants reaching bilaterally and percent bilateral contact time. Bilateral midline reaching is typically observed after the onset of unilateral midline reaching (van Hof, van der Kamp, & Savelsbergh, 2002). We analyzed bilateral contact data because manipulating an object with two hands versus one allows infants to use actions not possible with just one hand to gather more information about objects' properties (Ballesteros, Manga, & Reales, 1997; Provine & Westerman, 1979). A bilateral contact was recorded any time right- and left-handed object contacts overlapped. An infant was recorded as reaching bilaterally if this occurred more than 10 times total or more than 5 times in supine or vertical. The total time of overlap between right- and left-handed contacts was extracted from the data and analyzed to determine the percentage of time infants were interacting with the object using both hands.

Variables for Task 2: Using Arm Movements to Explore Objects

The percent time fingering or mouthing the exploration objects was coded and calculated. "Fingering" occurred when the opposite hand contacted the attached object. "Mouthing" occurred when the mouth or lips contacted the attached object. The time spent fingering or mouthing was totaled and then converted to a percentage of the total possible exploration time or the sum of the trial times (three 60-s trials and three 45-s trials for a total of 315 s).

Variables for Task 3: Using Arm Movements to Explore a Means – End Task

Our means – end task was similar to the one used by Munakata et al. (2002) in that infants acted on a switch to inflict consequences on another, more distant object in the environment that did not appear physically linked to the switch. We modeled Willatts's (1999) use of multiple variables, including behavior with the means object and visual fixation on the end object, to assess for intentional means – end behavior. Means – end behavior in this paradigm was defined based on four criteria involving the three variables that follow.

1. *Number of toy activations and nonactivations.* Coders recorded toy and nonactivations noting the time superimposed on the video. These data provided (a) the total number of switch activations (toy activations plus nonactivations), (b) the number of toy activations, and (c) the number of nonactivations for each means – end period.
2. *Percent of toy activations and nonactivations accompanied by visual attention to the toy.* Coders determined whether infants visually attended to the toy within 5 s of each switch activation. Visual attention to the toy was not coded more than 5 s from an activation because each event of toy activity only lasted 5 s. These data were compiled to determine the percentage of toy activations and nonactivations accompanied by visual attention to the toy in each period.
3. *Percent time with positive or negative/neutral affect.* Each 5-s interval of each means – end period was coded using A System for Identifying Affect Expressions by Holistic Judgments (AFFEX), a general scale of affect for infants and children (Izard, Dougherty, & Hembree, 1989). Infants' affect on this scale could be coded as interest, happy, sad, angry, fearful, or neutral. No periods of fearful affect were observed, so affect was grouped into positive (interest or happy) or negative (sad or angry)/neutral. These data were compiled to determine the percent of time in each period during which infants demonstrated positive or negative/neutral affect.

Means – end behavior during one means – end period. The means – end task challenged young infants to coordinate their visual attention and arm movements to explore the relationship between switch activations and distant toy activity while maintaining a positive affect. An infant was recorded as having demonstrated means – end behavior in a period if he or she met four criteria incorporating the three aforementioned variables: (a) infants must first actively reach to explore, so infants were required to have an average of greater than two total activations per minute during the period; (b) infants should then match their actions to the desired toy activity, so it was required that greater than two thirds of the total activations be toy activations during the period (E. J. Gibson, 1997); (c) positive affect accompanies periods of learning, so it was required that infants demonstrate positive affect greater than two thirds of the total time during the period (Lewis et al., 1990; Lewis, Hitchcock, & Sullivan, 2004); and (d) as a suggestion of whether infants were able to link their actions with the toy activity, infants were required to look at the toy within 5 s of greater than one half of the toy activations (Willatts, 1999). To demonstrate that the criteria captured behavior that was unique to toy activations, the same criteria were also applied to non-activations.

Means – end behavior during both means – end periods. To allow for a period of exploration after the change in the switch – toy activation relationship between periods, only the final 2 min of the second means – end period were analyzed in cases where means – end behavior occurred in the first means – end period of the visit. We analyzed toy activations as well as nonactivations to ensure that the criteria captured behavior unique to activations resulting in toy activation. The four means – end criteria remained the same.

Secondary Variables Related to Means – End Behavior (Task 3)

Anticipated differences in means – end behavior among groups could potentially be attributed to differential development among groups. That is, groups may not have been able to achieve the four individual means – end behavior criteria in a similar manner due to differential motor, perceptual, or affect regulation abilities. We tracked the following secondary variables to determine whether any means – end behavior differences among groups were due to more general differences in the motor, perceptual, or affective requirements of the means – end task.

1. *Numbers of infants completing the entire assessment.* Differences in means – end behavior could have been due to differential motor ability to activate the switches. This may have resulted in group differences in the numbers of infants completing the entire means – end assessment. The numbers of infants completing the entire means – end performance assessment were recorded for each visit.
2. *Ability to turn to visually attend to the toy location.* Differences in means – end behavior could have been due to differential motor ability to rotate one's head to attend to the location of the toy. The ability to turn to visually attend to the toy included any instance of head rotation to attend to the toy during the means – end assessment or to the toy's anticipated location during the reaching and exploration assessments. The numbers of infants demonstrating the motor ability to turn to visually attend to the toy location were recorded for each visit.
3. *Visual attention to the toy or switches.* Differences in means – end behavior could have been due to differential visual – perceptual performance or

object interest during the means – end task. This may have resulted in group differences in visual attention to the switch and toy (means and end) and in the coordination of toy activations with attention to the toy. The data on visual attention to the toy or switches describe infants' looking behavior throughout the entire assessment, providing a broader picture of looking behavior than solely analyzing attention to the toy at times of switch activations. The durations infants looked at the toy during the 30-s pre-means – end period and at the toy or switches during the means – end periods at each visit were coded, summed, and converted to a percentage of the total period time.

Statistical Analyses

Kruskall – Wallace (KW) analysis of variance (ANOVA) was performed for most between-group comparisons. If the resultant α was $\leq .05$, KW post hoc tests by ranks were performed. Fisher's exact test was performed for planned between-group comparisons of nominal variables. For within-group comparisons of secondary means – end performance variables, Friedman's ANOVA was performed because the same participants contributed to the data being compared. In all statistical analyses, $\alpha \leq .05$ represents significant results. When multiple results are presented within the same set of parentheses, the first *p* value in a set represents the three-way result and the following *p* values represent the results of comparisons between pairs of groups.

Results

There were no differences among groups in terms of age, days between visits, or amount of home experience. Infants in each group received a similar number of days of home experience (social experience: $M = 18.0$, $SD = 2.7$; postural experience: $M = 19.1$, $SD = 1.7$; object experience: $M = 16.9$, $SD = 2.1$) and a similar number of total minutes of home experience (social experience: $M = 304.1$, $SD = 146.6$; postural experience: $M = 263.2$, $SD = 64.9$; object experience: $M = 252.5$, $SD = 41.2$). As mentioned, provision of home experience was sufficient for inclusion in the study if it occurred on more than 60% of the days between Visit 1 and Visit 3 according to journal reports from parents. We chose this criterion based on pilot data from our previous intervention studies in which infants who received experiences less than 50% of the time did not appear different from control infants (Lobo et al., 2004). This percentage was not significantly different among groups (social experience: $M = 87.5$, $SD = 11.5\%$; postural experience: $M = 88.1$, $SD = 5.9\%$; object experience: $M = 78.2$, $SD = 10.5\%$).

Rating on the AIMS

AIMS ratings were not significantly different among the three groups at Visit 1, suggesting that infants began the study with similar levels of general motor development. Changes in AIMS ratings suggested that the postural experiences effectively advanced motor development by advancing postural stability. This was particularly the case for prone skills after the 3-week home experience period compared to both other groups and at the end of the study compared to the social experience group. The change in total AIMS rating from Visit 1 to Visit 6 was different among the groups and was significantly greater for postural experience infants than for social experience infants, $\chi^2(2, N = 42) = 6.27$, $ps = .04, .02$, respectively. The change in prone subscale rating from Visit 1 to Visit 3 was different among groups and was significantly greater for the postural experience infants than for infants in the social experience and object experience groups, $\chi^2(2, N = 42) = 7.18$, $ps = .03, .02, .03$, respectively. The change in prone subscale rating from Visit 1 to Visit 6 continued to be different among groups with a greater change for postural experience infants compared to social experience infants, $\chi^2(2, N = 42) = 7.72$, $ps = .02, .01$, respectively.

Task 1: Using Arm Movements to Reach

Number of Infants Reaching

A greater number of postural and object experience infants reached earlier than social experience infants (Table 1). More object experience infants reached than did social experience infants at Visits 3 and 4 (*ps* = .02, .01, respectively). More postural experience infants reached than did social experience infants at Visit 3 ($p = .03$). When separating the data from the supine and vertical positions, these group differences were more evident in the vertical position earlier for both the postural and the object experience groups (Visit 2: *ps* = .08, .006, respectively; Visit 3: *ps* = .03, .01, respectively; Visit 4: $p = .02$ for object experience) than in the supine position (Visit 3: $p = .02$ for object experience; Visit 4: $p = .05$ for postural experience; Visit 5: $p = .002$ for object experience). The total number of infants reaching in

Table 1

Total Numbers of Infants Reaching Unilaterally and Bilaterally Across Visits for the SE, PE, and OE Groups

	Visit number					
Group	1	2	3	4	5	6
Numbers of infants reaching unilaterally						
SE	0	2	3	6	10	13
PE	0	4	9[a]	9	12	14
OE	0	5	10[a]	13[a]	13	14
Numbers of infants reaching bilaterally						
SE	0	0	0	0	5	12
PE	0	1	3	4[a]	11[a]	11
OE	0	0	2	4[a]	13[a]	13

Note. SE = social experience; PE = postural experience; OE = object experience.

[a] Signifies a difference from the SE group, $p \leq .05$.

each group was greater in the vertical position than the supine position for each group from Visits 2 through 6.

Number and Duration of Object Contacts

Postural and object experience infants contacted the object more frequently at Visits 3–5 compared to social experience infants (Figure 4a). There were differences among groups for average number of contacts at Visits 3, 4, and 5, Visit 3: $\chi^2(2, N = 42) = 8.30, p = .02$; Visit 4: $\chi^2(2, N = 42) = 8.32, p = .02$; Visit 5: $\chi^2(2, N = 42) = 8.39, p = .02$. Object experience infants contacted the object more frequently than did social experience infants at Visits 3, 4, and 5 (*ps* = .003, .004, and .01, respectively). Postural experience infants contacted the object more frequently than did social experience infants at Visit 4 ($p = .03$). When separating the data from the supine and vertical positions, these group differences were more evident in the supine position earlier, Visit 2: $\chi^2(2, N = 42) = 7.58, p = .02$; Visit 3: $\chi^2(2, N = 42) = 10.15, p = .01$; Visit 5: $\chi^2(2, N = 42) = 13.34, p = .001$, than in the vertical position, Visit 4: $\chi^2(2, N = 42) = 9.84, p = .01$. Yet, the average number of contacts in each group was greater in the vertical position for every group from Visits 2 through 6.

Postural and object experience infants contacted the object for longer durations at Visits 2–4 compared to social experience infants (Figure 4b). There were differences among groups for duration per contact at Visits 2, 3, 4, and 6, Visit 2: $\chi^2(2, N = 370) = 23.47, p = .000$; Visit 3: $\chi^2(2, N = 777) = 21.99, p = .000$; Visit 4: $\chi^2(2, N = 1169) = 20.58, p = .000$; Visit 6: $\chi^2(2, N = 3042) = 13.54, p = .001$. Object experience infants contacted the object longer than did social experience infants at Visits 2 and 4 (*ps* = .002, .000, respectively). Object experience infants contacted the object longer than did postural experience infants at Visits 4 and 6 (*ps* = .05, .001, respectively). Postural experience infants contacted the object longer than did social experience infants at Visits 2, 3, and 4 (*ps* = .000, .002, .001, respectively). Postural experience infants contacted the object longer than did object experience infants at Visits 2 and 3 (*ps* = .01, .000, respectively). Social experience infants contacted the object longer than did the postural experience infants at Visit 6 ($p = .002$). When separating the data from the supine and vertical positions, these group differences were more evident earlier in the vertical position, Visit 2: $\chi^2(2, N = 27) = 31.93, p = .000$; Visit 3: $\chi^2(2, N = 467) = 15.81, p = .000$; Visit 4: $\chi^2(2, N = 906) = 18.27, p = .000$, than in the supine position, Visit 3: $\chi^2(2, N = 467) = 15.81, p = .000$. The average duration of contact in each group was similar in both positions for every group for the early visits but was longer in supine for the final visit.

Number of Infants Reaching Bilaterally and Percent Bilateral Contact Time

A greater number of postural and object experience infants reached bilaterally earlier than social experience infants (Table 1). More postural and object experience infants had bilateral object contacts than did social experience infants at Visits 4 and 5 (Visit 4: *ps* = .05, .05, respectively; Visit 5: *ps* = .03, .002, respectively). When separating the data from the supine and vertical positions, these group differences were more evident in the vertical position earlier for both the postural and object experience groups (Visit 4: *ps* = .04, .006, respectively; Visit 5: $p = .02$ for object experience) than in the supine position (Visit 5: $p = .05$ for both groups). The total number of infants reaching bilaterally in each group was greater in the vertical position for every group from Visits 2 through 6.

Postural and object experience infants spent more time bilaterally contacting the object at Visits 4 and 5 (Figure 4c). There were differences among groups at Visits 4 and 5 in terms of the percent time infants were bilaterally contacting the object, Visit 4: $\chi^2(2, N = 42) = 10.24, p = .01$; Visit 5: $\chi^2(2, N = 42) = 7.64, p = .02$. Both postural and object experience infants spent more time bilaterally contacting the object than did social experience infants at these visits (Visit 4: *ps* = .04, .001, respectively; Visit 5: *ps* = .05, .002, respectively). When separating the data from the supine and vertical positions,

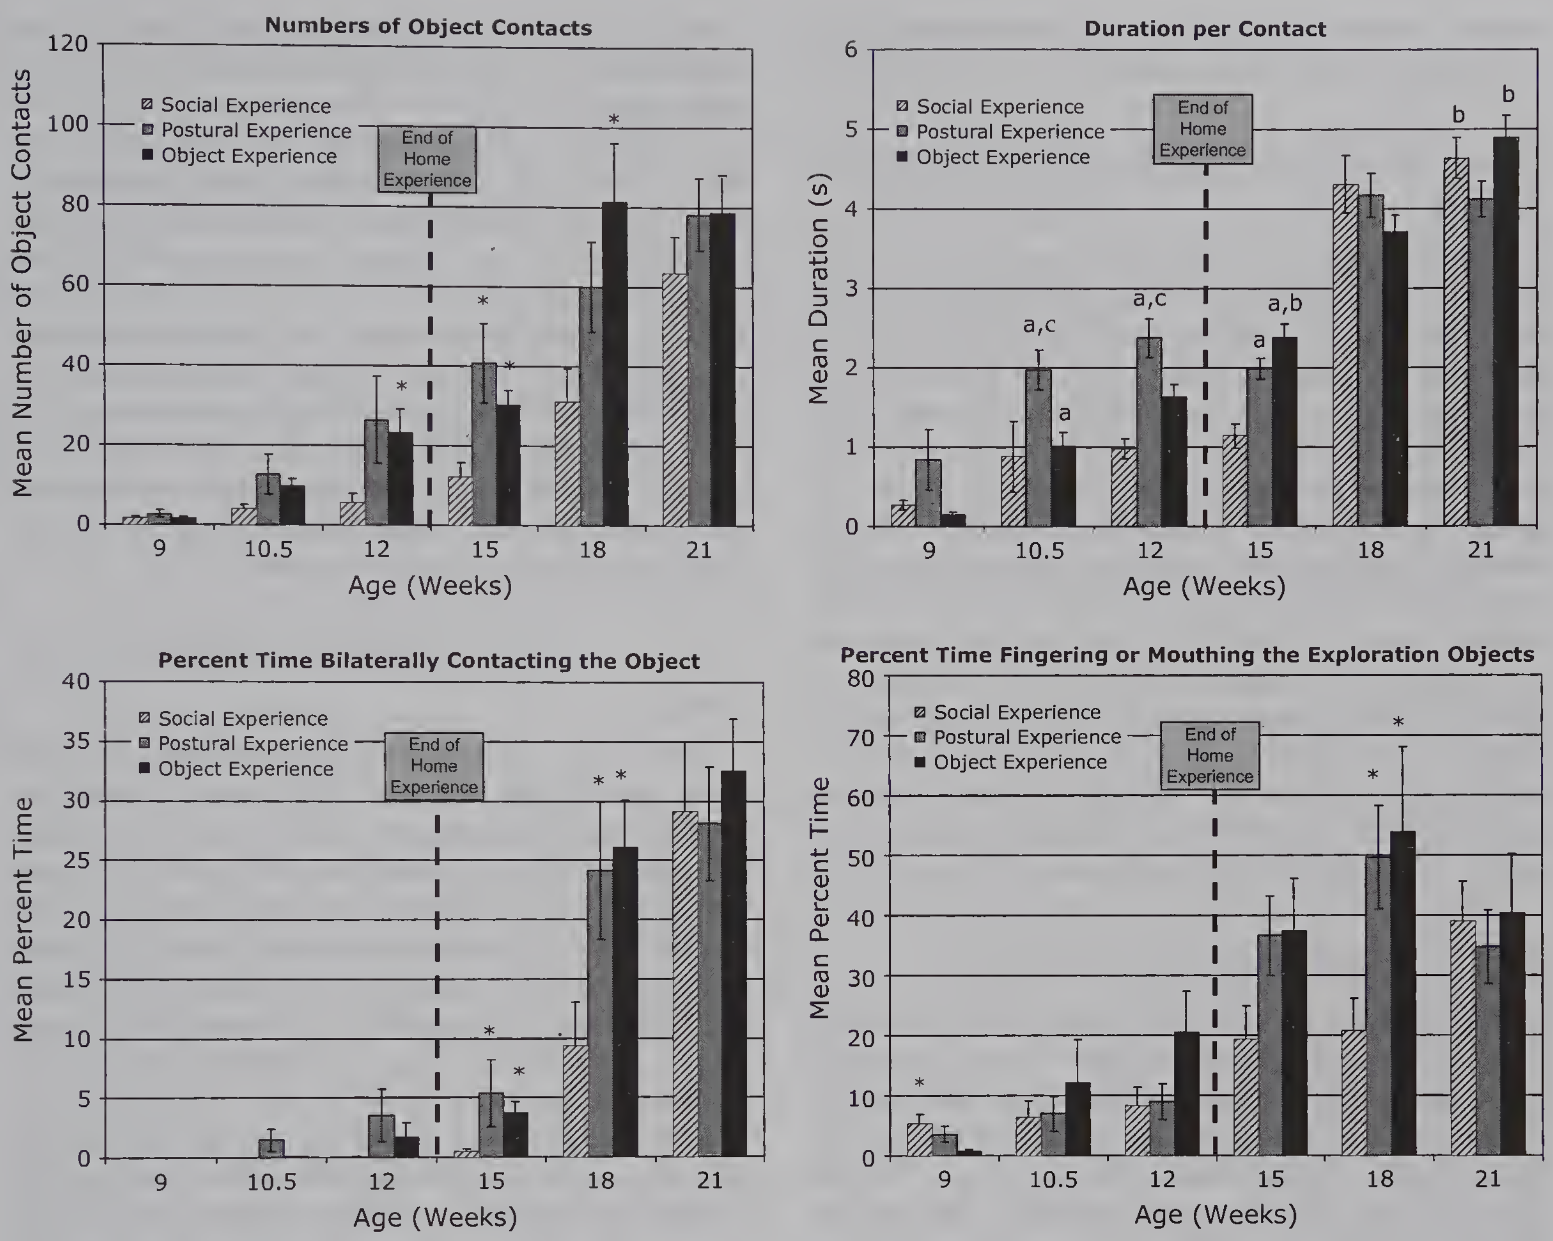

Figure 4. (a) Mean numbers of object contacts across visits for each group. (b) Mean durations per contact across visits for each group. these group differences were more evident in the vertical position earlier, Visit 4: $\chi^2(2, N = 42) = 9.60, p = .01$; Visit 5: $\chi^2(2, N = 42) = 6.08, p = .05$, than in the supine position, Visit 5: $\chi^2(2, N = 42) = 8.97, p = .01$. The average percent time spent bilaterally contacting the object in each group was greater in the vertical position for every group from Visits 2 through 6.

Task 2: Using Arm Movements to Explore Objects

Postural and object experience infants spent more time haptically exploring objects at Visit 5 than did social experience infants (Figure 4d). Infants in all groups increased the time they spent haptically exploring across the study, but at Visit 5, the postural and object experience groups spent more time fingering and mouthing the exploration objects than did the social experience group, $\chi^2(2, N = 42) = 8.20$, $ps = .02, .01, .04$, respectively. By the end of the study, infants in all groups were fingering and mouthing the exploration objects similarly.

Task 3: Using Arm Movements to Explore a Means – End Task

First, we report how each group performed during both means – end periods of a visit as well as the total number of periods in which infants displayed means – end behavior. We then report results from the secondary means – end variables.

Means – End Behavior During Both Means – End Periods of a Visit

Object experience infants demonstrated the best means – end behavior as evidenced by means – end behavior during both means – end periods of a visit. Table 2 shows the numbers of infants in each group demonstrating means – end behavior during both periods of the visit.

At Visit 6, more infants in the object experience group demonstrated means – end behavior during both periods of the visit than did infants in the social and postural experience groups (p = .049 for both comparisons). The object experience group also had the greatest total number of infants showing means – end behavior during both periods of a visit compared to the social experience group (p = .02). This means – end behavior was unique to toy activations. No infants in any group ever met the means – end behavior criteria for nonactivations during both periods of a visit.

Number of Periods With Means – End Behavior

Satisfying the means – end behavior criteria during just one means – end period of a visit does not demonstrate true means – end behavior. However, it does demonstrate emerging means – end behavior because this ability must be present in order for infants to show means – end behavior in both periods. Both the object and postural experience groups displayed more individual periods of means – end behavior than the social experience group. Specifically, the object and postural experience groups had greater numbers of total periods of means – end performance than the social experience group, $\chi^2(2, N = 42) = 6.31$, ps = .04, .02, .04, respectively. Object experience infants had 24 and postural experience infants had 21 periods of means – end behavior, whereas social experience infants had only 12 periods across all visits.

Table 2
Numbers of Infants Demonstrating Means – End Behavior During Both Means – End Periods of a Visit Across Visits and in Total for the SE, PE, and OE Groups

Group	Visit 1	Visit 2	Visit 3	Visit 4	Visit 5	Visit 6	Total
SE	0	0	0	0	0	0	0
PE	0	0	0	0	1	0	1
OE	0	0	0	0	1	4[a,b]	5[a]

Note. SE = social experience; PE = postural experience; OE = object experience.
[a]Signifies a difference from the SE group, $p \leq .05$. [b]Signifies a difference from the PE group, $p \leq .05$.

The total numbers of periods where infants met these criteria for nonactivations were significantly lower for all groups (social experience, 1 period; postural experience, 2 periods; object experience, 0 periods) than were the number of periods where infants met these criteria for toy activations, social experience: $\chi^2(1, N = 28) = 11.63$, $p = .001$; postural experience: $\chi^2(1, N = 28) = 16.82$, $p = .000$; object experience: $\chi^2(1, N = 28) = 20.96$, $p = .000$, and were not different among groups. This suggests that the performance criteria captured behaviors unique to exploration of the switch – toy means – end relationship.

Results for Secondary Variables Related to Means – End Behavior

This means – end task required the coordination of motor, perceptual, and affective aspects of behavior. Results from secondary measures help to rule out whether the means – end behavior results simply reflect group differences in these requirements. Ruling out these general differences would provide further support that means – end behavior differences resulted from varying abilities of the infants in each group to coordinate these abilities to perform a challenging task.

Motor requirements for the means–end task. Group differences in means – end behavior were not explained by differences in motor ability. Infants in each group developed the motor requirements for the means – end performance task similarly. Motor requirements for the task involved the ability to (a) activate the switches using arm movement and (b) turn to the side to view the toy using head movement.

1. *Switch activation*: Each group activated the switches enough to have similar opportunities to display means – end behavior. Specifically, there were no significant differences among groups in the number of infants meeting the switch activation criterion more than five switch activations in the first 2 min of the first means – end period) and subsequently completing the entire assessment at each visit. At least two thirds of infants in each group completed the entire assessment by Visit 3, and all infants did so by Visit 6.

In addition, each group activated the switches a similar number of times at each visit. Specifically, there were no significant differences among groups for the number of toy activations or nonactivations except at Visit 4. Postural and object experience infants had more toy activations and nonactivations at Visit 4 than did social experience infants, toy activations: $\chi^2(1, N = 28) = 7.45$, $ps = .02, .01, .05$, respectively; nonactivations: $\chi^2(1, N = 28) = 8.86$, $ps = .01, .01, .02$, respectively.

2. *Head turning to visually attend to the toy*: Each group had the ability to turn their head to the side where the toy was located at each visit. There were no significant differences among groups in the numbers of infants who turned their heads toward the toy location. The majority of infants in each group demonstrated this ability at Visit 1, and all infants in each group demonstrated this ability by Visit 3.

Perceptual requirements for the means–end task. Group differences in means–end behavior were not due to general differences in visual–perceptual ability, although there were some differences among groups. That is, infants in each group developed the perceptual requirements for the means–end task similarly. These requirements were the ability to visually attend to (a) the toy during the pre-means–end period and (b) the toy or switches during the means–end periods.

Each group increased its visual attention to the toy during the pre-means–end period across visits. Each group had similar ability and interest to maintain attention to the toy during the pre-means–end period at each visit except at Visit 6. At Visit 6, the groups were different with object experience infants attending more to the toy than infants in the postural experience group, $\chi^2(2, N = 42) = 5.79$, $ps = .05, .02$, respectively.

Each group increased its visual attention to the toy and switches during the means–end periods across visits. Each group had similar ability and interest to maintain attention to the toy or switches during the means–end periods at each visit except at Visit 6. At Visit 6, the groups were different and the object experience group spent more time looking at the toy than did the social and postural experience groups, $\chi^2(2, N = 42) = 7.70$, $ps = .02, .01, .04$, respectively.

It was expected that once infants understood the switch–toy relationship, they would spend increased time looking at the toy, a focal point of the means–end behavior (Willatts, 1999). Therefore, we wanted to analyze not only how much each group attended to the toy compared to the other groups but also how much time within each group involved looking at the toy versus the switches at each visit. The social and postural experience groups spent more time looking at the switches than the toy at every visit (Figure 5a), Visit 2: social experience $\chi^2(1, N = 14) = 10.00$, $p = .002$, postural experience $\chi^2(1, N = 14) = 9.31$, $p = .002$; Visit 3: social experience $\chi^2(1, N = 14) = 6.23$, $p = .01$, postural experience $\chi^2(1, N = 14) = 9.31$, $p = .002$; Visit 4: social experience $\chi^2(1, N = 14) = 13.00$, $p = .000$, postural experience $\chi^2(1, N = 14) = 14.00$, $p = .000$; Visit 5: social experience and postural experience $\chi^2(1, N = 14) = 14.00$, $p = .000$; Visit 6: social experience $\chi^2(1, N = 14) = 10.29$, $p = .001$, postural experience $\chi^2(1, N = 14) = 14.00$, $p = .000$. Infants in the object experience group showed this same pattern of looking until Visit 6, the visit where they demonstrated the greatest means–end performance, when they visually attended to the switches and the toy the same amount of time, $\chi^2(1, N = 14) = 10.29$, $p = .001$ for Visits 1–5.

Affect requirement for the means–end task. Group differences in means–end behavior were not explained by general differences in ability to regulate affect across visits. Each group met the means–end behavior affect requirement of maintaining a positive affect more than two thirds of the time in a period for the final three to four visits. Each group increased the time it maintained a positive affect across visits, and the duration of positive affect was not different among groups at each visit. Each group demonstrated more positive than negative/neutral affect from Visits 4 to 6 (Figure 5b), Visit 4: social experience, postural experience, and object experience $\chi^2(1, N = 14) = 7.14$, $p = .008$; Visit 5: social experience $\chi^2(1, N = 14) = 4.57$, $p = .03$, postural experience and object experience $\chi^2(1, N = 14) = 10.29$, $p = .001$; Visit 6: social experience and postural experience $\chi^2(1, N = 14) = 10.29$, $p = .001$, object experience $\chi^2(1, N = 14) = 14.00$, $p = .000$.

Motor–perceptual coupling requirement for the means–end task. Group differences in means–end behavior were explained, in part, by differences in motor–perceptual coupling abilities. Specifically, groups differed in their ability to meet the motor–perceptual coupling requirement of accompanying toy activations with visual attention to the toy.

The postural and object experience groups demonstrated selective motor–perceptual coupling behavior earlier than the social experience group. Groups did not differ in the percentage of toy activations accompanied by attention to the toy at each visit. However, true means–end behavior requires that infants do not simply randomly attend to the toy with any switch activation but rather that they selectively attend to the toy more often with toy activations than with nonactivations. We term this *selective*

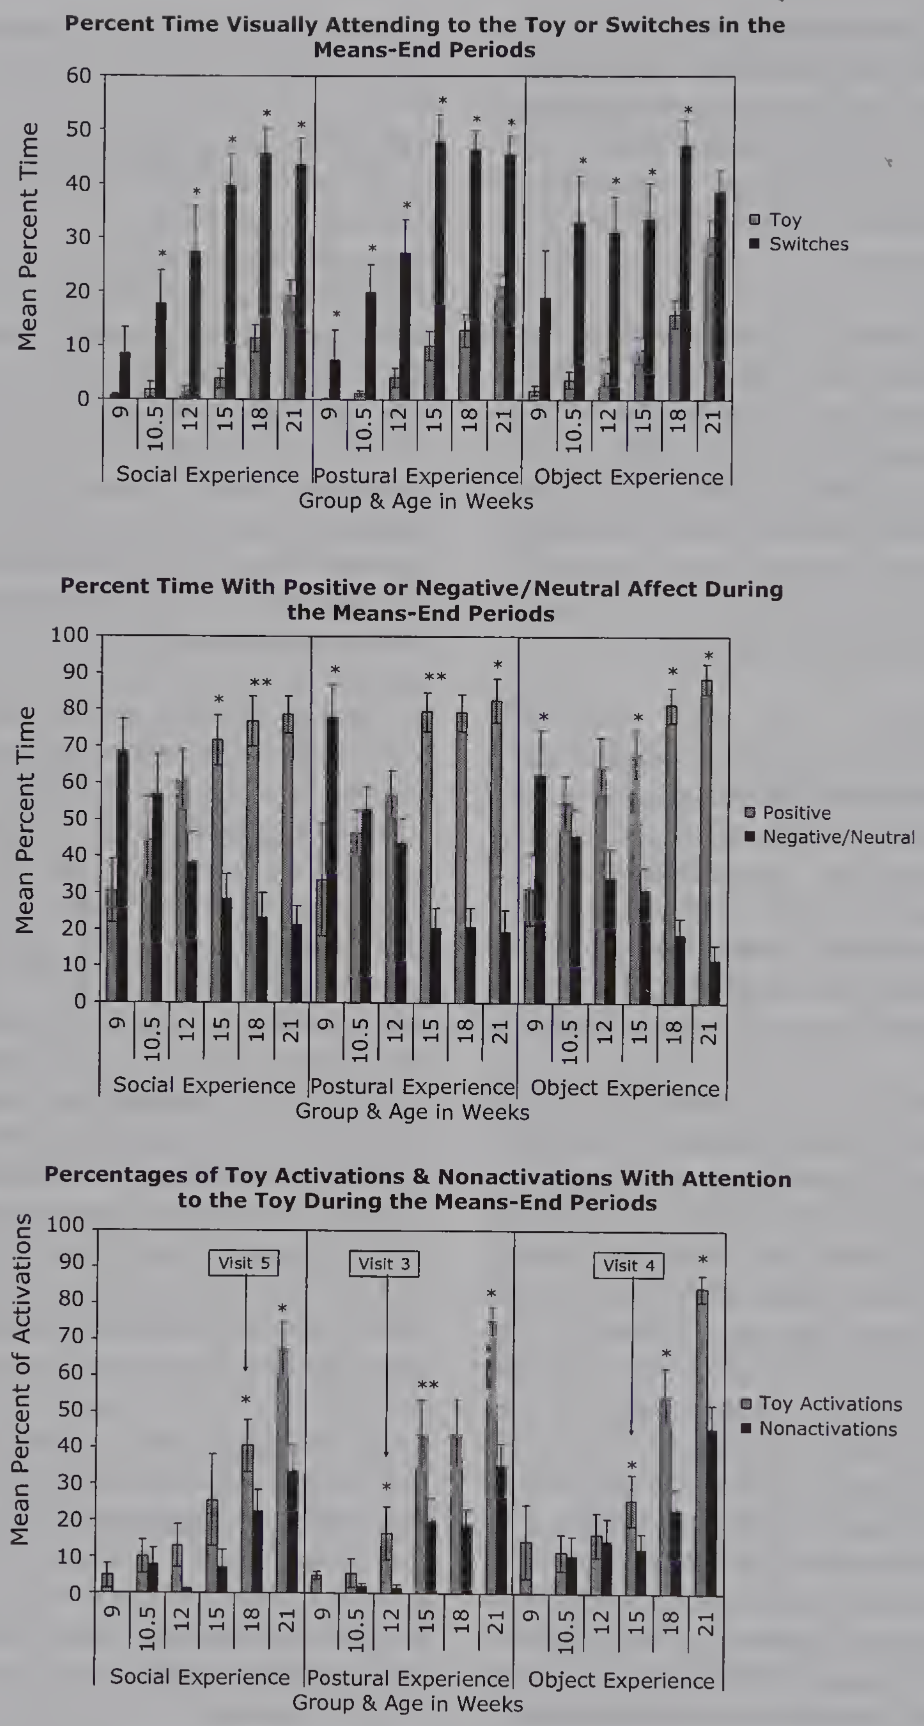

Figure 5. (a) Mean percent times each group attended to the toy or switches during the means–end periods across visits. (b) Mean percent times each group demonstrated positive or negative/neutral affect during the means–end periods across visits. (c) Mean percentages of toy activations and nonactivations for each group accompanied by attention to the toy during the means–end periods across visits.
Note. In Figure 5(a), note that the groups looked more at the switches except at Visit 6 when the object experience group looked similar amounts at the toy and switches. In Figure 5(b), note that each group increased positive affect and decreased negative/neutral affect over time without differences among groups. In Figure 5(c), note that the postural and object experience groups showed earlier selectivity of their motor–perceptual coupling than did the social experience group, attending to the toy more with toy activations than with nonactivations. Error bars reflect standard error of the mean.
$^*p \leq .05$.

motor–perceptual coupling. Indeed, group differences in this selective coupling emerged with greater attention to the toy with toy activations for postural experience infants by Visit 3 (Figure 5c), Visit 3: $\chi^2(1, N = 14) = 7.00, p = .01$; Visits 4 and 5: $\chi^2(1, N = 14) = 8.33, p = .004$; Visit 6: $\chi^2(1, N = 14) = 14.00, p = .000$, for object experience infants by Visit 4, Visit 4: $\chi^2(1, N = 14) = 8.33, p = .004$; Visit 5: $\chi^2(1, N = 14) = 9.308, p = .002$; Visit 6: $\chi^2(1, N = 14) = 14.00, p = .00$, and for social experience infants by Visit 5, Visit 5: $\chi^2(1, N = 14) = 10.00, p = .002$; Visit 6: $\chi^2(1, N = 14) = 7.14, p = .008$. In effect, the postural and object experience groups attended more often to the toy selectively with toy activations earlier than did the social experience group. This suggests that they had an earlier association between their actions on the switches and the activity of the toy.

Discussion

Summary of the Results

Postural and object experience infants had advanced reaching, exploration, and developing means–end behavior compared to social experience infants (Figure 6). Most of the group differences were observed after the 3-week prescribed home experience period ended at Visit 3. Differential ability to reach for and contact objects was the only change observed during the 3-week home experience period. Differences in reaching ability continued, and differences in object exploration and means–end behavior emerged weeks to months after the home experience period ended. Therefore, infants who had similar abilities at the first visit embarked on different developmental trajectories even after their prescribed home experience period ended. Specifically, postural and object experience infants had more frequent object contacts at Visits 2–5, longer contact durations at Visits 2–4, more bilateral contact time at Visits 4 and 5, more haptic object exploration at Visit 5, and greater numbers of periods of developing means–end behavior primarily at Visits 5 and 6 compared to social experience infants. The object experience group had the greatest number of infants demonstrating means–end behavior in both periods at Visit 6.

Task 1: Postural and Object Experience Infants Had Advanced Reaching Emergence and Ability

Postural and object experience infants had earlier onsets for reaching and advanced reaching ability compared to social experience infants. The differences in reaching ability among the three groups suggest that the emergence of reaching is dependent on multiple interacting subsystems and can be similarly advanced by experiences that affect a variety of these subsystems (Bertenthal & von Hofsten, 1998; Hopkins & Ronnqvist, 2002; Thelen, 1990; Thelen et al., 1993; von Hofsten, 1993). This supports and extends our previous work showing that the emergence of reaching can also be advanced via experiences to increase arm flapping (Lobo et al., 2004).

This study is the first to demonstrate that reaching emergence can be advanced by the provision of advanced postural experiences. This builds on previous work showing that experience being placed in different postures, such as sitting or standing, can

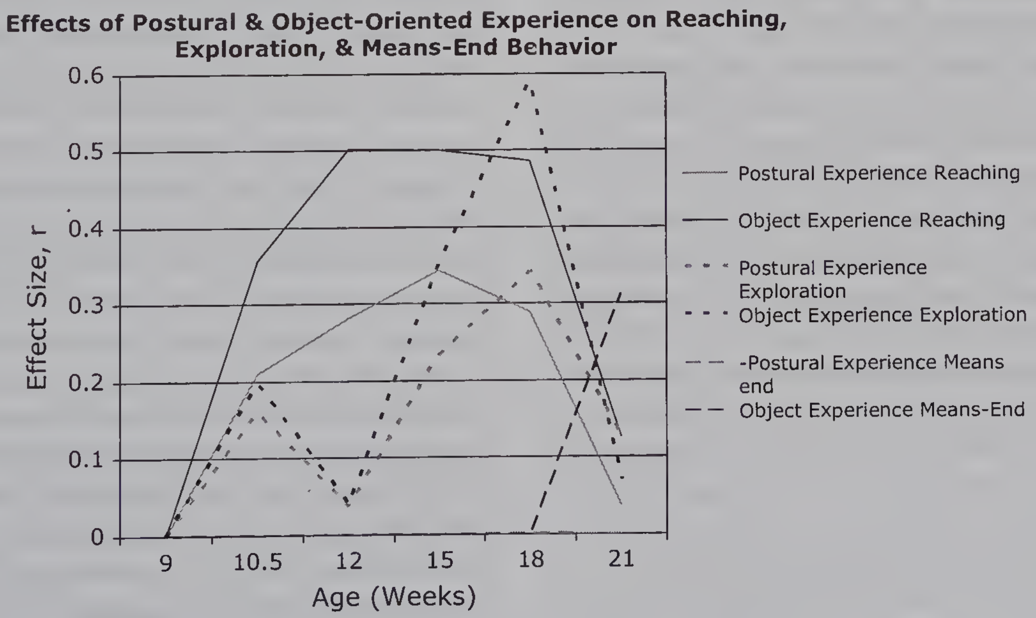

Figure 6. Effects of postural and object-oriented experiences on reaching, exploration, and means–end behavior represented by effect size, *r*.
Note. A value of zero indicates no difference in behavior from the social experience group.

directly advance infants' abilities to maintain these postures (Bril & Sabatier, 1986; Hopkins & Westra, 1988, 1989, 1990; Zelazo et al., 1993). This work was unique, however, in that the goal of the experiences was to directly advance postural stability, whereas our focus was whether this would then advance the unpracticed behavior of reaching.

To understand how postural experiences led to the emergence of reaching, we must consider factors both internal and external to the infants. Parents of postural experience infants were asked to provide infants with opportunities to improve their postural stability by placing and moving them in a variety of postures. This occurred during the supine, spontaneous, and social period when infants spend much of their time supine (Davis et al., 1998; Mildred et al., 1995). Ratings on the AIMS suggest that postural experience advanced infants' postural stability across postures. Postural experience infants likely had improved head and trunk strength and control for visual exploration and reaching, more appropriate muscle responses to maintain balance, and increased perceptual – motor experiences in a variety of positions (Bril & Sabatier, 1986; Thelen & Spencer, 1998; Wijnroks & van Veldhoven, 2003; Witherington et al., 2002). In addition, we suspect that as parents observed their infants' abilities to maintain different postures and to begin to reach for objects, they likely switched their parent – infant – object interactions to "postures, purpose, and play" earlier than typically reported (Fogel, 1997; Fogel et al., 1999; Reed & Bril, 1996). This switch was likely influenced by the effects of the postural experiences but was not assigned as part of the prescribed experiences. As a result, postural experience infants likely had early, increased opportunities to improve their postural stability across positions and to interact with objects throughout each day (Bertenthal & von Hofsten, 1998; Eppler, 1995). It is likely that such changes within infants combined with changes in parent handling and interaction to advance reaching ability in infants provided with postural experiences.

To understand how object-oriented experiences led to the emergence of reaching, we must again consider factors both internal and external to the infants. Parents of object experience infants were asked to provide their infants with opportunities and assistance to reach for and explore objects (Fogel, 1997; Fogel et al., 1999; Lobo et al., 2004). This occurred during the supine, spontaneous, and social period when parents primarily interact with infants face-to-face with little active object exploration (Fogel et al., 1999). Object experience infants likely had improved movement control in a midline task space, motivation to reach for objects presented, and knowledge that objects presented within reach afford haptic exploration. In addition, as parents observed their infants' abilities to reach for, grasp, and mouth objects, they likely switched their parent – infant – object interactions to "purpose and play" earlier than typical (Fogel, 1997; Fogel et al., 1999; Reed & Bril, 1996). Consequently, object experience infants likely had increased opportunities to interact with objects on a daily basis even outside of the prescribed home experience periods (Bakeman et al., 1990; Bruner, 1972). The home experience for these infants was provided in supine, and these infants did not advance in their postural stability according to AIMS ratings as did postural experience infants. In fact, their changes in total and subscale AIMS scores were not different from social experience infants. This suggests that parents of object experience infants did not provide infants the same advanced opportunities to improve their postural stability across positions as did parents of postural experience infants.

Social experience infants did not have advanced reaching ability. By Visit 6, however, their reaching abilities were similar to infants in the two advanced experience groups. The experiences parents of these infants provided involved face-to-face interactions in supine, the type of interaction most common during the supine, spontaneous, and social period (Davis et al., 1998; Fogel et al., 1999; Mildred et al., 1995). Therefore, it was expected that reaching development in these infants would mirror typical development. In fact, social experience infants began reaching at an average of 18.25 ± 1.81 weeks of age, which is within the 4- to 5-month-old period typically reported (Thelen et al., 1993; von Hofsten, 1991). Consequently, social experience infants likely did not transition to postures, purpose, and play and have increased opportunities to interact with objects on a daily basis until after their onset of reaching at Visit 5 (Eppler, 1995; Fogel, 1997; von Hofsten, 1997).

More infants were able to contact the object more frequently with one hand as well as bilaterally earlier and throughout the study in the vertical position compared to supine. The average duration per contact was not different between the vertical and supine positions throughout the study but was greater in the supine position by the end of the study. These data support the proposal that it is easier for young infants to initiate reaches but more difficult to sustain contact with objects in a vertical position (Carvalho et al., 2007; Savelsbergh & van der Kamp, 1994). In supine, infants may find it more challenging to initiate reaches but easier to sustain contacts with objects due to the effects of gravity on the arm's biomechanics. When the hand is farther away from the center of mass, infants must produce more muscle force to overcome gravitational force. This is the case when reaches are initiated in supine with the hands resting laterally on the floor and in trying to sustain contacts in vertical with the hands held in front of the trunk.

In this study, two distinct experiences advanced reaching ability. These results support the idea that even the earliest behaviors emerge as the result of a dynamic process involving the coordination of multiple interacting subsystems encompassing task, environmental, and organismic factors (Bertenthal & von Hofsten, 1998; Corbetta & Bojczyk, 2002; Hopkins & Ronnqvist, 2002; Joh & Adolph, 2006; Lee, Liu, & Newell, 2006; Thelen, 1990; Thelen et al., 1993; von Hofsten, 1993). Acceleration of the development of one or more of these subsystems can advance the ontogeny of early object interaction behavior (Lobo et al., 2004). For this study, we suspect that advancing parent – infant – object interactions, head and trunk control, postural stability, and / or perceptual – motor experiences across positions may have advanced reaching development.

Task 2: Postural and Object Experience Infants Had Advanced Haptic Exploration of Objects

Postural and object experience infants demonstrated advanced haptic exploration of objects compared to social experience infants. These results suggest that haptic exploration of objects is dependent on infants' past experiences, the emergence of reaching, as well as ongoing daily parent – infant – object interactions (Berthier, Rosenstein, & Barto, 2005; Bourgeois et al., 2005; J. J. Gibson, 1962, 1966; Millar, 2005; Needham, 2000; Needham et al., 2002). This is the first study presenting empirical evidence for a link between the onset of reaching and later haptic object exploration across developmental time. It is important to note that increased haptic exploration of objects did not occur until the weeks after reach onset in all groups. These results are particularly interesting given that at the start of the study, infants already demonstrated the ability to bring their hands to their mouths for mouthing and to one another for fingering of the objects attached to their wrists (Rochat, 1989).

What might young infants learn from haptic exploration of objects? First, information processing via haptic exploration provides infants with knowledge about properties of objects, such as hardness, texture, and shape, which cannot be accurately detected by vision alone (Ballesteros et al., 1997; Carello, Grosofsky, Reichel, Solomon, & Turvey, 1989; Case-Smith et al., 1998; Turvey, 1996). This knowledge base allows older infants to discriminate and categorize objects of varying characteristics (Booth, 2006; Bourgeois et al., 2005; Ellis & Oakes, 2006; Palmer, 1989; Ruff, 1984). Yet, infants have weeks to months of experience haptically exploring objects before this discrimination ability emerges (Case-Smith et al., 1998; Rochat, 1989). Besides knowledge about physical properties of objects, what could infants be learning from these early exploration experiences?

Even before infants are able to discriminate physical properties of objects, it has been proposed that they are able to learn what actions those objects afford (E. J. Gibson, 2000). The fact that infants did not use their available movements to explore the Velcroed objects until after the onset of reaching suggests that haptic exploration of objects may in itself be a global affordance that young infants must learn (Bourgeois et al., 2005; J. J. Gibson, 1962, 1966; Millar, 2005; Needham, 2000; Needham et al., 2002). Infants at each visit were shown the exploration objects before trials began, but they disregarded the objects at early visits before they were consistently reaching. For instance, most infants spent less than 10% of the time exploring objects haptically across the first few visits, whereas at the final visit, most infants spent about 40% of the time exploring objects haptically (Figure 4d). Object exploration in this paradigm did not require grasping as objects were Velcroed to infants' wrists. It was as if prereaching infants did not yet realize that they could use their existing arm movements to haptically explore objects. We propose that as young infants begin to reach for, grasp, and transport objects, they learn to match these new action abilities to objects to learn that objects of certain sizes and shapes afford mouthing and fingering (Case-Smith et al., 1998; E. J. Gibson, 2000; Millar, 2005). Then, via early, frequent, active haptic exploration of a range of objects, infants learn more about how to adapt and refine their actions to more specifically match the various properties of objects (Adolph et al., 2000; Ballesteros et al., 1997; Bourgeois et al., 2005; Needham et al., 2006). For instance, infants may later learn that in addition to mouthing and fingering, objects such as rattles and spoons afford sound production and food transport. In effect, learning that some objects can be explored haptically may be the first step in the process of gaining object knowledge required for future object categorization and discrimination.

Task 3: Object and Postural Experience Infants Had Advanced Means – End Behavior

Object experience infants had the most sophisticated means – end behavior, evidenced by means – end behavior during both periods of a visit. Postural experience infants had better developing means–end behavior than social experience infants, evidenced by a greater number of periods of means–end behavior. These results suggest that the developmental origins of means–end behavior may lie in the ongoing motor, perceptual, and cognitive experiences associated with early reaching and object exploration (Bremner, 2000; E. J. Gibson & Pick, 2000; Menard, 2005; Piaget, 1952, 1954; von Helmholtz, 1962). These results highlight the critical role action performance on objects plays in the development of means–end behavior and expand the view that early knowledge development relies primarily on perceptual and cognitive changes (Baillargeon, 1987; Johnson, Slemmer, & Amso, 2004).

Our results suggest that means–end behavior emerges after infants are able to coordinate their motor, perceptual, and affect regulation abilities. Specifically, there were no differences in the individual motor, perceptual, or affect regulation abilities among groups that can fully account for the results. This supports Willatts's (1999) idea that intentional means–end behavior involves the coordination of multiple variables. In our task, infants had to display a greater frequency of toy activations in coordination with looking to the toy while maintaining a positive affect (Lewis et al., 1990; Munakata et al., 2002; Willatts, 1999). Infants' abilities to coordinate these emerging abilities across domains to perform in a novel task are a hallmark of means–end behavior.

Our results support the idea that means–end knowledge is gained in part via active exploration of objects (Bremner, 2000; Piaget, 1952). E. J. Gibson (1997) suggested that infants learn by first performing exploratory activity, then observing the consequences of this activity, and finally selecting from the activities explored. She viewed trial-and-error experience as essential to learning. This type of activity is exactly what infants were required to do to explore the means–end relationship within our paradigm. To learn, infants were required to explore the switches via reaching, observe that movement of one switch resulted in distant toy activity, and then repeatedly select the behavior that resulted in that toy activity by activating that switch more frequently than the other.

Our results provide the first empirical support for the idea that the emergence of means–end behavior is in part dependent on the amount of previous object exploration. Object experience infants had increased opportunities to explore objects from Visit 1, and they demonstrated the most sophisticated means–end behavior. Postural experience infants began reaching and likely had increased opportunities to explore objects from Visit 3 and had more advanced developing means–end behavior than social experience infants. Social experience infants began reaching and likely had increased opportunities to explore objects late in the study from Visit 5 and had the poorest means–end behavior.

The results of this study provide important data on the developmental origins of the means–end behavior so often observed in older infants (Bojczyk & Corbetta, 2004; Goubet, Rochat, Maire-Leblond, & Poss, 2006; Munakata et al., 2002). Using a means–end task such as the one presented here that calls on infants to coordinate abilities they already possess to demonstrate that means–end knowledge may help avoid the performance competency issue encountered by other behavioral means–end studies (Bremner, 2000; Matthews, Ellis, & Nelson, 1996). Means–end paradigms such as ours that capitalize on infants' existing behaviors may help researchers avoid the challenge of comparing violation of expectancy paradigms with behavioral paradigms (Bremner, 2000; Hood, 2001; Munakata et al., 2002; Shinskey, Bogartz, & Poirier, 2000; Sommerville & Woodward, 2005). Future studies can build upon these results to tests for developmental connections between early associative learning and memory paradigms such as Rovee and Rovee's (1969) mobile paradigm and later assessments of object exploration and means–end behavior.

Implications for Developmental Theory and Intervention

The developmental relationships among the three behaviors investigated in this study and the ways the prescribed experiences affected these behaviors support theories of development proposing actions as the foundation for perceptual and cognitive development (Bremner, 2000; E. J. Gibson, 2000; J. J. Gibson, 1979; Piaget, 1952; von Helmholtz, 1962). Our results also have implications for intervention for infants with developmental delay. First, the results support the premise that early intervention can advance the emergence of a behavior (Heathcock et al., 2008; Lobo et al., 2004; Ulrich, Ulrich, Angulo-Kinzler, & Yun, 2001; van Beek, Hopkins, Hoeksma, & Samsom, 1994). Postural and object experiences provided to infants with special needs may be able to advance reaching (Heathcock et al., 2008), just as experience walking supported on a treadmill can advance the emergence of walking in infants with Down syndrome (Ulrich et al., 2001). Although therapeutic interventions often begin in early infancy and frequently rely on techniques attempting to advance postural stability or object interaction, we are not aware of any prospective studies directly relating such controlled movement interventions to advanced behavioral outcomes in infants less than 6 months of age. Second, providing early experiences for one skill may advance development of a range of motor, perceptual, and cognitive abilities (Hack & Taylor, 2000; van Beek et al., 1994). Perhaps similar advancements across developmental domains could be achieved by advancing other early behaviors. For instance, language development may be advanced via experiences to advance early object banging or gesturing (Iverson & Fagan, 2004; Iverson & Goldin-Meadow, 2005) or later problem-solving ability could be advanced via experiences to broaden the ranges of exploratory behaviors young infants perform on various objects (Caruso, 1993). Although most therapists would agree that skill attainment generally advances development across domains, there is little empirical support for this idea in early infancy (Needham, 2000).

In summary, the behavior of infants in this study provides empirical support that (a) the development of novel behaviors is dependent on multiple subsystems and can be similarly advanced by addressing a variety of these subsystems (Bertenthal & von Hofsten, 1998; Hopkins & Ronnqvist, 2002; Thelen, 1990; von Hofsten, 1993); (b) reaching ability can be indirectly advanced via activities to improve postural stability; (c) parent–infant interactions play a critical role in early development and can be altered to advance development (Bakeman et al., 1990; Bruner, 1972; Cintas, 1995; Landry & Chapieski, 1988); (d) reaching, object exploration, and means–end behavior are developmentally related behaviors that can all be advanced via experiences aimed at advancing reaching; and (e) past experiences with active object exploration can facilitate early information processing and the development of early knowledge (Ballesteros et al., 1997; Bremner, 2000; E. J. Gibson & Pick, 2000; Needham, 2000).

A Process Model of Attachment–Friend Linkages: Hostile Attribution Biases, Language Ability, and Mother–Child Affective Mutuality as Intervening Mechanisms

Nancy L. McElwain

University of Illinois at Urbana–Champaign

This study identified mechanisms through which child–mother attachment security at 36 months was associated with mother- and teacher-reported friendship quality at 3rd grade. Data from a subsample of 1,071 children (536 boys) participating in the National Institute of Child Health and Human Development Study of Early Child Care and Youth Development were used. Separate structural equation models were tested for mother and teacher reports of peer functioning. For both models, the total indirect effect between attachment security and friendship quality was significant. Tests of specific indirect effects indicated that attachment security was associated with friendship quality via greater mother–child affective mutuality and better language ability at 54 months and fewer hostile attributions (teacher model only) and greater peer competence at first grade. The findings highlight interpersonal and intrapersonal mechanisms of attachment–friend linkages.

Establishing and maintaining close friendships is a central developmental task of middle childhood, yet the quality of children's friendships varies widely (Hartup, 1996). Although not the only contributor to friendship quality, the intimate, dyadic nature of attachment relationships is posited to be especially germane to children's close relationships, such as friendships, compared with more general indices of social adjustment (see Belsky & Cassidy, 1994; Sroufe & Fleeson, 1986; Thompson, 1998). In line with this view, child–mother attachment security has been related in theoretically expected ways to children's friendship quality (e.g., Elicker, Englund, & Sroufe, 1992; McElwain, Cox, Burchinal, & Macfie, 2003; McElwain & Volling, 2004; Youngblade & Belsky, 1992), and in a meta-analysis of attachment–peer associations, Schneider, Atkinson, and Tardiff (2001) reported a larger effect size for studies of children's close friendships versus studies of children's interactions with unfamiliar peers (also see Lieberman, Doyle, & Markiewicz, 1999). We aimed to further this line of inquiry by assessing potential intervening mechanisms of attachment–friend linkages.

Our investigation was guided by attachment theory, in which Bowlby (1969/1982) proposed that children continuously construct "working models" of self, other, and relationships through repeated interactions with caregivers. The internal working model, in turn, mediates associations between early attachment relationships and later outcomes through the formation of expectations or rules for behavior (see Bretherton & Munholland, 1999) and the filtering of the individual's attention and memory in ways that are consistent with his or her expectations for interpersonal interactions (see Main, 1995; Main, Kaplan, & Cassidy, 1985). Notably, patterns of verbal and nonverbal communication between the caregiver and the child, especially about emotions, are considered central to the development and maintenance of working models of attachment (Bowlby, 1969/1982, 1988; Bretherton, 1990; Kobak & Duemmler, 1994; Main et al., 1985). From birth, caregivers respond to their infant's vocal and nonvocal cues, and these caregiver–infant exchanges—repeated over time—lay the

foundation for nascent working models of self and other (Ainsworth, Blehar, Waters, & Wall, 1978). During the preschool years, the attachment relationship is transformed by the child's burgeoning language and cognitive skills, and Thompson (2000) proposed that it is during this period of representational advance that working models of attachment may be especially influential in predicting child functioning. In light of these propositions, we assessed children's hostile attribution biases and language ability as intervening mechanisms linking child–mother attachment security at 36 months and children's friendship quality at Grade 3. Furthermore, open emotional communication between mothers and children, which we refer to here as affective mutuality, was examined as an interpersonal process through which child–mother attachment security would be associated with intrapersonal processes (i.e., hostile attributions, language ability) and ultimately friendship quality.

Hostile Attribution Biases

Dodge and colleagues' (Crick & Dodge, 1994; Dodge, Pettit, McClaskey, & Brown, 1986) model of social information processing (SIP) includes several steps (e.g., encoding and interpreting social cues, generating and evaluating potential responses) that are expected to influence an individual's response to a social stimulus. We focus here on attributions of hostile intent when interpreting social cues because this SIP construct, in particular, parallels the notion of the internal working model as an interpretative filter (e.g., Main, 1995). The utility of hostile attributions as an intervening mechanism of attachment–friend linkages is also suggested by studies linking hostile attributions to a host of peer-related outcomes, including aggression (see Orobio de Castro, Veerman, Koops, Bosch, & Monshouwer, 2002), peer rejection (Feldman & Dodge, 1987), friendship quality, and social competence (Webster-Stratton & Lindsay, 1999).

Importantly, the SIP model highlights "latent mental structures" as the individual's scripts, schemata or cognitive heuristics of previous experiences that have been integrated into long-term memory and that guide processing of social stimuli (Crick & Dodge, 1994; Dodge & Schwartz, 1997). Reliance on latent mental structures, which is especially likely when social stimuli are ambiguous, allows for more efficient, schema-consistent processing of environmental cues but may also lead to errors or distortions (Baldwin, 1992; Crick & Dodge, 1994). The SIP notion of latent mental structures echoes Bretherton and Munholland's (1999) discussion of the internal working model as event schemas or scripts. Thus, the child's internal working model (or latent mental structures), which emerges from repeated interactions with attachment figures, is expected to guide online interpretation of social stimuli. For instance, guided by a working model of the self as worthy of care and others as supportive and trustworthy, a child with a secure attachment history may make benign attributions about negative interpersonal events in which the intent of the other is ambiguous. In contrast, a child with an insecure attachment history, and corresponding working model of the self as unworthy and others as unresponsive, may be more likely to attribute hostile intentions to others. In other words, a child who has received repeated rejection and hostility from attachment figures may come to expect such treatment from others, even when situational cues do not merit such expectations.

Of the few studies investigating associations between attachment and hostile attribution biases, evidence has been mixed. Suess, Grossmann, and Sroufe (1992) reported that an insecure–avoidant infant–mother attachment was associated with attributions of negative peer intent at age 5 (but see Cassidy, Kirsh, Scolton, & Parke, 1996; Ziv, Oppenheim, & Sagi-Schwartz, 2004, for null findings), and Cassidy et al. (1996) found that attachment security during the early school years was concurrently related to more positive attributions of peer intent. Little is known about preschool attachment security as a predictor of hostile attribution biases. As highlighted by Crittenden (1990), working models move from reliance on procedural memories during infancy to integration of semantic memories during late toddlerhood. Unlike procedural memories, semantic memories are conscious, rely on language for encoding and recall, and are likely to be elicited when information is ambiguous. Because these developmental changes result in more complex and language-mediated working models, attachment security during the early preschool period may be particularly important for setting in motion attributional biases that, in turn, impact later functioning (see also Thompson, 2000).

Only one study, to our knowledge, has tested SIP biases as a mechanism of attachment–friend associations. Cassidy et al. (1996, see study 2) examined a composite of peer representations measured via Dodge and Frame's (1982) SIP task as a mediator of concurrent associations between child–mother attachment security and number of reciprocal friendships in the kindergarten or first-grade classroom. No evidence of mediation was found. Rather, attachment security and peer representations were each significant predictors of the outcome, but only when entered first in the model. The small sample and concurrent measurement of the predictor, mediator, and outcome variables may have hindered detection of mediation in the Cassidy et al. study. The current study addressed these limitations.

Language Ability

In highlighting the role of communicative processes for developing attachment relationships, attachment theorists have considered the bidirectional influence of attachment and language. The child's emerging language skills are expected to transform his or her attachment relationships, and attachment relationships may also forecast the child's competence in acquiring and using language (Bowlby, 1969/1982; Bretherton, 1990; Main et al., 1985). This latter possibility is further suggested by research underscoring the social foundations of language acquisition (e.g., see Tomasello, 1992) and the notion that, from an evolutionary standpoint, language may be rooted in vocal behaviors aimed at fulfilling relational goals (Locke, 2001). Although few researchers have investigated attachment security as an antecedent of language competence, van IJzendoorn, Dijkstra, and Bus (1995) conducted a meta-analytic review of seven studies and reported a substantial association (r = .28) between infant–mother attachment security and greater language ability. Moreover, examining data from the National Institute of Child Health and Human Development (NICHD) Study of Early Child Care and Youth Development (SECCYD), Belsky and Fearon (2002) found that secure infant–mother attachment was associated with language comprehension at 36 months, controlling for contextual risk. Language and attachment researchers alike have suggested that the child's interactions with a sensitive, responsive caregiver may account, to some extent, for the better language abilities of children with a history of secure attachment (e.g., Cohen, 2001; Fish & Pinkerman, 2003; van IJzendoorn et al., 1995).

Language also underpins key processes of childhood friendship formation and maintenance, including establishing a common ground, constructing joint plans, coordinating play, and negotiating resolutions to conflict (Gottman, 1983; Howes, Droege, & Matheson, 1994; Parker & Gottman, 1989). Not surprisingly, then, language difficulties have been related to lower social competence and poorer quality friendships (see Farmer, 2006), whereas higher levels of expressive and receptive language abilities have been associated with more positive, cooperative peer interactions (e.g., Mendez, Fantuzzo, & Cicchetti, 2002) and more socially connected interactions with friends (e.g., Hebert-Myers, Guttentag, Swank, Smith, & Landry, 2006). Given the importance of verbal communication for children's relationships with attachment figures and friends, we investigated child language ability as a second intervening mechanism.

Mother–Child Affective Mutuality

Affective mutuality (i.e., the balanced, free-flowing verbal and nonverbal exchange of emotions) is a core characteristic of secure attachment relationships. With the advent of language, open verbal communication about emotions has the potential to foster the child's feelings of security, exploration of his or her inner world, and effectiveness in coping with negative emotions (Bowlby, 1988; Bretherton, 1990; Kobak & Duemmler, 1994; Main et al., 1985). In contrast, exchanges in which the attachment figure censures, negates, or distorts the child's emotional experience are expected to have negative consequences for child well-being due to conflicting working models (e.g., what is experienced vs. what is said), impoverished exploration of attachment-related thoughts and feelings, and difficulty integrating and updating working models of self and other. Accordingly, infant–mother attachment security has been associated longitudinally with more emotionally open and coherent mother–child communication, whereas a history of insecure attachment has been associated with communication that is rigid, restricted, and less coherent (e.g., Etzion-Carasso & Oppenheim, 2000; Main et al., 1985). Likewise, attachment security assessed during the preschool years has been related to more frequent, elaborative discourse about negative emotions during mother–child talk about past events (Farrar, Fasig, & Welch-Ross, 1997; Laible, 2004). Open emotional exchange between mothers and children, in turn, has been related to children's higher levels of language and concept development (Pianta, Nimetz, & Bennett, 1997), greater social competence (Pianta et al., 1997), and more constructive coping strategies (Gentzler, Contreras-Grau, Kerns, & Weimer, 2005). In sum, mother–child affective mutuality may be an important interpersonal process through which attachment security is associated with intrapersonal competencies.

The Current Study

In assessing hostile attributions, language ability, and affective mutuality as mechanisms of attachment–friend linkages, we used data from the NICHD SECCYD. Model A in Figure 1 presents the hypothesized process model. This model posits chains of indirect pathways from child–mother attachment

Figure 1. Model A: Children's hostile attributions and language ability (54 months and Grade 1) and mother–child affective mutuality (54 months) as intervening mechanisms between child–mother attachment at 36 months and friendship quality at Grade 3. Model B: Peer competence at Grade 1 as an additional intervening mechanism.
Note. FQ-Pos = friendship quality, positive interaction subscale; FQ-Neg = friendship quality, negative interaction subscale.

security and affective mutuality to hostile attributions and language ability and from hostile attributions and language ability to friendship quality, which is conceptualized as high levels of positive features and low levels of negative features (Berndt, 2002). We expected that mother–child affective mutuality, as an interpersonal process, would influence friendship quality via intrapersonal processes (i.e., hostile attributions, language ability). Moreover, a secondary aim was to assess the degree to which 36-month attachment security was related to mechanisms in Grade 1 via mother–child affective mutuality at 54 months.

The model is guided by strong theoretical assumptions regarding the causal nature and temporal ordering of constructs. In real time, the child–mother relationship is expected to precede and shape the child's attributional biases and language abilities, which, in turn, are expected to precede and shape the child's behavior and relationships with others. Furthermore, the longitudinal design and repeated assessments of constructs permit an analysis of change over time, and this "replicative strategy" (Hoyle & Robinson, 2004) is considered optimal when testing intervening mechanisms in nonexperimental studies (e.g., see Cole & Maxwell, 2003).

We also examined alternative indirect pathways in which peer competence in Grade 1 was part of the chain of intervening mechanisms (see Model B in Figure 1). Fewer hostile attributions (see Crick & Dodge, 1994) and better language skills (see Farmer, 2006) have been associated with social adjustment, and these proposed mechanisms may be associated with friendship quality via peer competence. Furthermore, during interactions with a sensitive, emotionally open caregiver, children may learn skills such as reciprocity and empathy (Elicker et al., 1992; Lieberman, 1977), which foster peer competence and, in turn, high-quality friendships. These alternative indirect paths were added to Model A to examine whether their addition significantly improved model fit.

Mother and teacher reports were used to assess peer competence in Grade 1 and friendship quality in Grade 3. Mother–teacher agreement on children's social competence and peer functioning tends to be modest (see Renk & Phares, 2004), and discrepancies may be due, in part, to differences in child behavior and/or peer partners across home and school contexts. Hence, we tested the process model separately for mother and teacher reports, and we explored in follow-up analyses whether the strength of paths predicting peer competence and friendship quality differed by reporter.

Finally, child gender was examined as a moderator of the process model. "Moderated mediation" occurs when an intervening process varies as a function of a third variable (Muller, Judd, & Yzerbyt, 2005). We expected attachment security to relate to hostile attributions and language ability similarly for girls and boys, yet associations between these variables and friendship quality may differ by gender. Because girls tend to be more interpersonally oriented (e.g., Leaper, 1991), the model may be stronger for girls. On the other hand, research on hostile attributions has largely focused on boys, and it is unknown whether associations between hostile attributions and peer outcomes are stronger for boys (Orobio de Castro et al., 2002).

Method

Participants

Participants were a subsample of 1,071 families drawn from the larger sample of 1,364 families participating in the NICHD SECCYD. Families were recruited from hospitals located in or near 10 sites across the United States and were screened on numerous criteria (e.g., mothers aged 18 years and younger were excluded from the study; all infants were healthy; see NICHD Early Child Care Research Network [ECCRN], 1997, 1999, for further details). The subsample examined in the current report had complete data on mother and/or teacher reports of friendship quality in third grade.

The demographic characteristics for the subsample are presented in Table 1. On average, mothers were 28.49 years of age and had received 14.44 years of education, as reported by mothers when study children were 1 month of age. The income-to-needs ratio (averaged across data collected at 6, 15, 24, and 36 months) was 3.72, indicating that overall family income was, on average, 3.72 times that of the poverty level. In assessing maternal partner status, mothers were asked at 1, 6, 15, 24, and 36 months whether they were currently living with a partner or husband. For 76% of the families, a partner or spouse lived in the home at all time points. Fifty percent of the study children were male. With respect to child ethnicity, 78% were European American non-Hispanic, 11% were African American non-Hispanic, 6% were Hispanic, and 5% were another race or more than one race.

Overview of Procedure

Child–mother attachment was assessed using a modified Strange Situation procedure at 36 months, and mother–child affective mutuality was assessed from a series of mother–child interactive tasks at 54 months. For coding purposes, all videotapes for a given assessment were shipped to a central site, and different coding teams (who were blind to participant characteristics and other study results) assessed child–mother attachment security and affective mutuality. Child interviews were conducted at 54 months and Grade 1 to assess hostile attributions and language ability. Mothers and teachers completed questionnaires assessing children's peer competence at Grade 1 and friendship quality at Grade 3.

Mother–Child Relationship

Attachment security. At 36 months, the modified 17-min Strange Situation procedure developed by Cassidy and Marvin (1992) was used to assess child–mother attachment security. This procedure took place in a laboratory playroom and consisted of five episodes: (a) a 3-min warm-up period, (b) a 3-min separation from mother, (c) a 3-min reunion with mother, (d) a 5-min separation, and (e) a second 3-min reunion. Like the Ainsworth et al. (1978) system for coding infant attachment, the Cassidy and Marvin system emphasizes the child's behavior during the reunion episodes, and children were classified into

Table 1
Descriptive Statistics on Demographic and Study Measures for Cases Included Versus Excluded

Measures	Cases included		Cases excluded	
Demographic measures	*N*	*M* (*SD*)	*N*	*M* (*SD*)
Maternal age	1,071	28.49 (5.58)	293	26.74 (5.62)
Maternal education	1,071	14.44 (2.45)	292	13.47 (2.59)
Income-to-needs ratio	1,063	3.72 (2.82)	239	3.17 (3.03)
	N	*n* (%)	*N*	*n* (%)
Child sex (male)	1,071	536 (50)	293	169 (58)
Child ethnicity (European American non-Hispanic)	1,071	833 (78)	293	209 (71)
Partner in home (yes)	1,068	807 (76)	274	185 (68)
Study measures (time point, source)	*N*	*M* (*SD*)	*N*	*M* (*SD*)
Attachment security (36 months, observed)	983	5.07 (1.70)	157	4.78 (1.83)
Affective mutuality (54 months, observed)	965	5.22 (1.25)	75	4.77 (1.54)
Hostile attribution bias (54 months, child)	938	1.70 (1.33)	75	1.96 (1.31)
Hostile attribution bias (Grade 1, child)	974	4.70 (2.05)	51	4.53 (1.77)
Language ability (54 months, child)	979	101.28 (14.61)	81	98.07 (15.89)
Language ability (Grade 1, child)	970	106.36 (16.09)	50	105.16 (15.94)
Peer competence (Grade 1, mother)	980	15.67 (2.70)	49	16.08 (2.67)
Peer competence (Grade 1, teacher)	956	15.31 (3.63)	45	15.13 (3.22)
Positive friendship (Grade 3, mother)	1,008	3.22 (0.34)	—	
Negative friendship (Grade 3, mother)	1,008	1.97 (0.48)	—	
Positive friendship (Grade 3, teacher)	955	3.15 (0.39)	—	
Negative friendship (Grade 3, teacher)	960	1.89 (0.53)	—	

Note. Cases were included in this report if complete data were available for mother- and/or teacher-reported friendship quality in Grade 3 (*N* = 1,071). For this reason, no excluded cases had data on the friendship outcomes. Data on maternal age and education were collected at 1 month. Data on income-to-needs ratio were collected at 6, 15, 24, and 36 months and combined across time points. Data on the presence of a partner in the home were collected at 1, 6, 15, 24, and 36 months and combined across time points.

groups that parallel the infant classificatory system. In addition to classifying children as secure, avoidant, dependent/resistant, and controlling/disorganized, coders rated global security on a 9-point scale, ranging from 1 (*highly insecure*; e.g., highly avoidant, ambivalent, or disorganized or displaying a combination of strategies) to 9 (*highly secure*; e.g., highly at ease in initiating interaction, proximity, or contact; during reunion, child is calm but pleased to see mother return). Three coders were trained and certified by Jude Cassidy. Prior to official coding, all coders assessed the ABCD classifications on a set of 21 test tapes and achieved at least 75% agreement with Dr. Cassidy. For official coding, interobserver reliability was assessed on 75% of the protocols, and disagreements were resolved by consensus. For the attachment classifications (ABCD), intercoder agreement (before consensus) was 75.7% ($\kappa = .58$). For the global rating of security, intercoder agreement assessed via intraclass correlations (Winer, 1971) was .73.

An assessment of construct validity revealed consistent, albeit modest, associations with multiple indicators of maternal and child functioning (NICHD ECCRN, 2001). Moreover, post hoc comparisons among the four attachment groups revealed differences between the secure group and the various insecure groups; no differences emerged among the insecure groups. Because this measure shows validity in distinguishing between secure and insecure attachment, only the continuous rating of security was used in this report. We examined the security continuum (vs. binary score) because it provides a more fine-grained assessment of security.

Affective mutuality. During a laboratory visit at 54 months, mother–child interaction was videotaped during a 15-min semistructured observation. Mothers and children were presented with three activities: (a) completing a maze using an Etch A Sketch, (b) building a series of same-sized rectangular cube towers from variously shaped blocks, and (c) playing with a set of six hand puppets. The first two activities aimed to capture mother–child interaction during challenging situations in which the tasks were too difficult for the child to complete on his or her own, and the third activity aimed to capture mother–child play.

Videotapes of the mother–child interactions were coded for mother and child behaviors (see NICHD

ECCRN, 2003). Given the emphasis on attachment security in this report, we examined the rating of dyadic affective mutuality, which was based on work by Pianta (1994). Affective mutuality was coded on a 7-point scale, ranging from 1 (*very low*) to 7 (*very high*), and captured the degree to which mothers and children engaged in open verbal and nonverbal exchange of emotions. High affective mutuality characterized dyads in which the mother acknowledged the child's emotions and vice versa, the mother and child shared positive and negative experiences, and the child was free to express positive or negative feelings. In contrast, low affective mutuality characterized dyads in which the mother dampened the child's expression of emotion, and mother – child exchanges, especially around negative emotions, were nonreciprocal or stifled. Approximately 23% of the tapes were randomly assigned to two coders. Interobserver reliability, assessed via intraclass correlations (Winer, 1971), was .87. Mother – child affective mutuality as measured here has been related to more peer social skills and fewer behavior problems as reported by kindergarten teachers (Pianta et al., 1997).

Hostile Attribution Biases

Fifty-four months. Children's hostile attribution biases were assessed during a 54-month laboratory visit. Children were presented with four stories (without pictures) involving a same-sex peer: (a) having a special toy taken by another child, (b) being hit by a ball, (c) being tripped, and (d) having grape juice spilled on the child. For each story, the intent of the peer was ambiguous, and the child was asked to choose from one of two attributions (e.g., "Did Tom hit you in the back by accident or did Tom want to hit you in the back?"). Children received a score of 1 for indicating that the peer's action was intended, and responses were summed across vignettes to form a *hostile attribution* score (α = .64). This measure, adapted from the cartoon version developed by Dodge et al. (1986), was modified specifically for use with 4-year-old children (Feshbach, 1990). Hostile attributions assessed via this method have been associated with behavior problems, social competence, and child – friend interaction (Feshbach, 1990; Webster-Stratton & Lindsay, 1999).

First grade. During a laboratory visit at first grade, the Attribution Bias Interview was administered (Dodge et al., 1986). Children were presented with eight cartoon drawings of peer provocations, in which the intent of the peer was ambiguous. For each situation, children were asked how they would interpret the peer's intent ("Why do you think this happened?") and how they would respond in such a situation ("What would you do?"). The first question assessed attributions of intent and was coded as don't know, nonhostile, or hostile. A hostile attribution score was computed by summing hostile responses across stories (α = .64). This measure of hostile attributions has been associated with greater aggressive behavior and peer rejection (e.g., Dodge et al., 1986) and lower levels of prosocial behavior (Nelson & Crick, 1999).

Language Ability

The Woodcock – Johnson Psychoeducational Battery – Revised (WJ – R) was administered to children during laboratory visits at 54 months and first grade. The WJ – R consists of two batteries: Tests of Cognitive Abilities (WJ – R COG) and Tests of Achievement. The Picture Vocabulary Test (Test 6 of WJ – R COG) was examined for purposes of the current report. The first six items were presented in a multiple-choice format, in which children were asked to point to a named object. For subsequent items, children were asked to name pictured objects. The WJ – R has been normed on a nationally representative sample of 6,359 participants ranging in age from 24 months to 95 years and has shown good internal consistency and test – retest reliability (McGrew, Werder, & Woodcock, 1991). Standardized scores were examined in the analyses.

Peer Competence

The Social Skills Questionnaire from the Social Skills Rating System (SSRS; Gresham & Elliott, 1990) was administered to mothers (Parent Form) and teachers (Teacher Form) at Grade 1. This questionnaire consists of 49 items assessing the frequency of social behaviors, and items were rated on a 3-point scale, ranging from 0 (*never*) to 2 (*very often*). A peer competence subscale was computed by summing 10 items that tapped children's prosocial behavior toward peers and appropriate response to negative peer interactions (αs = .74 and .85, mothers and teachers, respectively). The SSRS has been normed on large samples and shows good construct validity and reliability (Gresham & Elliott, 1990).

Friendship Quality

The Quality of Child's Friendship questionnaire was administered to mothers and teachers at third grade. This 20-item questionnaire, which assesses the child's relationship with a best friend, was adapted from the Quality of Classroom Friends questionnaire

(Clark & Ladd, 2000). Twelve items assessed positive interaction ($\alpha = .88$ for both mothers and teachers) and 8 items assessed negative interaction (αs = .85 and .86, mothers and teachers, respectively). Items were rated on a 4-point scale, ranging from 1 (*strongly disagree*) to 4 (*strongly agree*). Subscales were computed by averaging across items. Clark and Ladd (2000) reported that kindergarten children who had more connected parent – child relationships tended to have more harmonious relationships with their closest friend as rated by teachers.

Data Analytic Strategy

Mplus 5.0 (Muthén & Muthén, 1998 – 2007) was used to test the hypothesized models. Full information maximum likelihood (FIML) was used to handle missing data. FIML offers less biased estimates compared with other methods such as listwise deletion (Enders & Bandalos, 2001; Schafer & Graham, 2002). To avoid inflating predictor – outcome associations, however, only cases with complete data on mother- and/or teacher-reported friendship quality were used in the analyses. The comparative fit index (CFI) and root mean square error of approximation (RMSEA) were examined to assess model fit. CFI values of 0.90 and above indicate an adequate fit, and values of 0.95 and above indicate a good fit (Hu & Bentler, 1995). RMSEA values less than 0.08 indicate adequate fit, and values less than 0.05 indicate a good fit (Browne & Cudeck, 1993). Maternal education and family income-to-needs ratio were included as covariates in all models presented below.

Model A and Model B depicted in Figure 1 were each estimated for mother and teacher reports of peer functioning (peer competence in Grade 1 and friendship quality in Grade 3). In testing Model B, three paths were added to Model A: 54-month hostile attributions, language ability, and mother – child affective mutuality to Grade 1 peer competence. Chi-square values for the two models were compared to determine the more plausible model. Error variances for manifest variables within the 54-month and Grade 1 time points were allowed to correlate, although for ease of presentation, the within-time covariances are not shown. For each model, the two subscales of the Quality of Child's Friendship questionnaire were indicators of a latent variable of friendship quality. Item ratings for the negative interaction subscale were reflected and averaged so that higher scores indicated greater friendship quality. For the more plausible model (Model A vs. Model B), total and specific indirect effects between child – mother attachment security at 36 months and friendship quality at Grade 3 were tested in Mplus using the delta method (i.e., Sobel, 1982). Because a secondary objective was to assess whether preschool attachment was associated with the proposed mechanisms via open emotional communication of the mother – child dyad, we also examined indirect effects between 36-month attachment security and Grade 1 mechanisms via mother – child affective mutuality at 54 months.

Two sets of follow-up analyses were conducted for the more plausible model. First, to examine child gender as a potential moderator of the indirect effects between attachment security and friendship quality, multigroup analyses were conducted. If a multigroup analysis indicated a significant gender effect, we assessed whether specific indirect effects between attachment security and friendship quality differed for boys and girls. Second, we examined mothers and teachers in the same model to compare path estimates predicting mother- versus teacher-reported peer competence in Grade 1 and friendship quality in Grade 3.

In assessing the proposed process model, it is important to distinguish between mediated and indirect effects. A mediated effect, which is considered a special case of indirect effects (Holmbeck, 1997; Preacher & Hayes, 2004), requires a significant association between the predictor and the outcome (Baron & Kenny, 1986). An indirect effect, in contrast, does not necessitate significance of this path. Rather, a significant indirect effect implies that the predictor has an effect on the outcome via the intervening variable (Kenny, Kashy, & Bolger, 1998). An examination of indirect effects may be especially important for developmental researchers examining processes that are distal in time (Shrout & Bolger, 2002). In this vein, we conducted a preliminary test of a "direct effects" model in which 36-month attachment security was the sole predictor of Grade 3 friendship quality (controlling for maternal education and family income). These analyses indicated that for both mother- and teacher-reported friendship quality, the direct effect of 36-month attachment security on friendship quality was nonsignificant. Thus, in the analyses that follow, we refer to indirect rather than mediated effects. Although Baron and Kenny's (1986) method for assessing mediation has been prevalent in the psychological literature, the importance of indirect effects, especially when examined across a long time span, should not be discounted because it is the predictor – mediator and mediator – outcome associations (vs. the predictor – outcome association) that are central to testing hypotheses concerning intervening mechanisms (Kenny et al., 1998).

Results

Preliminary Analyses

Cases included in the current report ($N = 1{,}071$) were compared to cases excluded due to missing data on either mother- or teacher-reported friendship quality in third grade (see Table 1 for descriptive statistics). Comparisons indicated that, on average, mothers included in the subsample were older, $t(1{,}362) = 4.74, p < .001$, and had received more years of education, $t(1{,}361) = 5.94, p \leq .001$. Participating families had a higher income-to-needs ratio, $t(1{,}300) = 2.67, p < .01$, and were more likely to have a partner living in the home, $\chi^2(1, N = 1{,}342) = 7.32, p < .01$. Furthermore, children included in the subsample were more likely to be female, $\chi^2(1, N = 1{,}364) = 5.37, p < .05$, and European American, $\chi^2(1, N = 1{,}364) = 5.30, p < .05$. Comparisons on the study measures indicated that included cases had higher levels of child–mother attachment security at 36 months, $t(1{,}138) = 1.96, p = .05$, and mother–child affective mutuality at 54 months, $t(1{,}038) = 2.94, p < .01$ (see Table 1 for means). Cases included versus excluded did not differ significantly on hostile attributions or language ability at 54 months and first grade nor mother- or teacher-reported peer competence at first grade.

For descriptive purposes, correlations among the study measures are presented in Table 2. Bivariate correlations are shown above the diagonal, and partial correlations controlling for maternal education and family income-to-needs ratio are shown below the diagonal.

Tests of the Process Model

The hypothesized process model depicted in Model A (see Figure 1) was tested separately for mother and teacher reports. Chi-square tests were significant, which would be expected given the large sample size: $\chi^2(20) = 68.57, p < .001$, and $\chi^2(20) = 54.65, p < .001$, mother and teacher models, respectively. Fit indices for Model A indicated good fit: RMSEAs = 0.048 and 0.040, CFIs = 0.973 and 0.978, mother and teacher models, respectively. Next, we tested Model B (see Figure 1) in which paths from 54-month hostile attributions, language ability, and mother–child affective mutuality to Grade 1 peer competence were added to Model A. Chi-square tests were again significant: $\chi^2(17) = 44.08, p < .001$, and $\chi^2(17) = 34.52, p < .01$, mother and teacher models, respectively. Fit indices for Model B indicated good fit for both mother and teacher models: RMSEAs = 0.039 and 0.031, CFIs = 0.985 and 0.989. Comparisons between Model A and Model B indicated that Model B showed significantly improved fit over Model A, $\chi^2_{\text{diff}}(3) = 24.49$ and 20.13, $ps < .001$, mother and teacher models, respectively. Because Model B was the more plausible model, we proceeded by examining the parameter estimates and testing indirect effects for Model B only. Standardized path estimates and R^2 values for mother and teacher models are presented in Figure 2. For paths not involving mother or teacher reports (e.g., path from 36-month attachment security to 54-month hostile attributions), path estimates were identical or nearly identical (i.e., differed at the third decimal place) across the mother and teacher models. Thus, for those paths, only one

Grade 1 Peer Competence

Figure 2. Hostile attributions, language ability, affective mutuality, and peer competence as intervening mechanisms between child – mother attachment at 36 months and friendship quality at Grade 3.

Note. Models (N = 1,071) were estimated separately for mother and teacher reports of peer functioning using full information maximum likelihood. Item ratings for FQ-Neg were reflected and averaged so that higher scores indicated greater friendship quality. For those paths predicting peer competence in Grade 1 and friendship quality in Grade 3, standardized path estimates for mother reports are presented outside parentheses, and standardized path estimates for teacher reports are presented inside parentheses. For all other paths, estimates were identical across mother and teacher models, and only one estimate is shown. Paths represented by dotted lines were nonsignificant for both mother and teacher models. R^2 estimates are presented for each endogenous variable. Maternal education and family income-to-needs ratio were included as covariates in the models. For ease of presentation, error terms, within-time covariances, and covariates are not shown. A table including these additional parameter estimates is available from the first author. FQ-Pos = friendship quality, positive interaction subscale; FQ-Neg = friendship quality, negative interaction subscale.
$^*p < .05$. $^{**}p < .01$. $^{***}p < .001$.

estimate (applicable to both mother and teacher models) is presented in Figure 2. For paths to mother- and teacher-reported peer competence in Grade 1 and friendship quality in Grade 3, estimates for the mother model are presented outside parentheses, and estimates for the teacher model are presented inside parentheses (see Figure 2).

The test of the total indirect effect (i.e., all specific indirect effects combined) from 36-month attachment security to Grade 3 friendship quality was significant for mother (z = 3.72, $p < .001$) and teacher (z = 3.40, p = .001) models. Next, we summarize results for each intrapersonal mechanism, in turn, with a focus on the tests of specific indirect effects between (a) attachment security and Grade 3 friendship quality and (b) attachment security and Grade 1 mechanisms via mother – child affective mutuality at 54 months.

Hostile attributions. As seen in Figure 2, child – mother attachment security at 36 months did not predict 54-month hostile attributions, although attachment security was indirectly related to Grade 1 hostile attributions via mother – child affective mutuality at 54 months (zs = −2.87 and −2.88, ps < .01, mother and teacher models, respectively). Furthermore, Grade 1 hostile attributions predicted lower friendship quality as reported by teachers in Grade 3, and this specific indirect effect (36-month attachment security→54-month affective mutuality→Grade 1 hostile attributions→Grade 3 teacher-reported friendship quality) was significant (z = 1.98,

$p < .05$). In contrast to the teacher model, Grade 1 hostile attributions were not significantly related to mother-reported friendship quality in Grade 3.

Language ability. Greater child–mother attachment security at 36 months was associated with greater language ability at 54 months, which, in turn, was associated with greater language ability at Grade 1 (see Figure 2). Moreover, 36-month attachment security had an indirect effect on Grade 1 language ability via mother–child affective mutuality at 54 months ($zs = 3.24$ and 3.26, $ps = .001$, mother and teacher models, respectively). Language ability in Grade 1, however, was not associated with friendship quality in Grade 3 as reported by mothers or teachers. Therefore, specific indirect effects of attachment security on friendship quality via Grade 1 language ability were nonsignificant.

Peer competence. For both mother and teacher models, affective mutuality and language ability, but not hostile attributions, at 54 months were associated with Grade 1 peer competence (see Figure 2). Furthermore, indirect effects of attachment security on peer competence emerged via 54-month affective mutuality ($zs = 3.26$ and 2.48, $ps < .001$ and .05, mother- and teacher-reported peer competence, respectively) and 54-month language ability ($zs = 2.14$ and 2.26, $ps < .05$). Grade 1 peer competence, in turn, was associated with greater mother- and teacher-reported friendship quality in Grade 3 (see Figure 2). Tests of the following indirect effects were significant: (a) 36-month attachment security → 54-month affective mutuality → Grade 1 peer competence → Grade 3 friendship quality ($zs = 3.09$ and 2.37, $ps < .01$ and .05, mother and teacher models, respectively) and (b) 36-month attachment security → 54-month language ability → Grade 1 peer competence → Grade 3 friendship quality ($zs = 2.09$ and 2.17, $ps < .05$).

Follow-Up Analyses

Child gender. We examined gender as a moderator of Model B. Multigroup analyses indicated that the unconstrained versus constrained model provided an improved fit for the mother model only, $\chi^2_{\text{diff}}(27) = 45.56$, $p < .05$. Given the effect of child gender for the mother model, we proceeded to examine specific indirect pathways for boys and girls. Comparisons revealed that the following indirect effects were significant for boys but not for girls: (a) attachment security → affective mutuality → peer competence, $\chi^2_{\text{diff}}(2) = 8.68$, $p < .05$ ($z = 3.34$, $p = .001$, for boys; $z = 0.85$, *ns*, for girls) and (b) attachment security → affective mutuality → peer competence → friendship quality, $\chi^2_{\text{diff}}(3) = 14.47$, $p < .01$ ($z = 2.73$, $p < .01$, for boys; $z = 0.85$, *ns*, for girls). Inspection of the individual paths composing these indirect effects indicated that the path from mother–child affective mutuality to mother-reported peer competence was significant for boys only ($\beta = .23$, $p < .001$, for boys; $\beta = .04$, *ns*, for girls).

Mother–teacher comparisons. Next, mother and teacher reports of peer competence and friendship quality were examined in one model to assess whether the strength of the path estimates differed by reporter. For a given predictor–outcome association (e.g., Grade 1 hostile attributions to Grade 3 friendship quality), mother and teacher paths were constrained to be equal, and we assessed whether model fit showed a significant improvement when the paths were free to vary. Of the six comparisons made (three paths to mother- vs. teacher-reported peer competence in Grade 1 and three paths to mother- vs. teacher-reported friendship quality in Grade 3), no significant differences emerged.

Discussion

Early attachment relationships are hypothesized to guide children's later interactions with others, especially close others, via internal working models of the self, other, and relationships. Despite the centrality of this premise to attachment theory, little is known about mechanisms that may account for associations between child–mother attachment security and children's subsequent close relationships with peers. To this end, we tested models of attachment–friend linkages using data from the NICHD SECCYD. Our hypothesized model, guided by attachment theory, posited hostile attribution biases and language ability as intrapersonal mechanisms through which attachment security at 36 months would be associated with children's friendship quality in third grade (see Model A, Figure 1). An alternative model considered peer competence in Grade 1 as part of the chain of intervening mechanisms (see Model B, Figure 1). Models were tested separately for mother- and teacher-reported peer functioning (peer competence and friendship quality), and in each case, the second model (Model B) provided a better fit to the data. Because open emotional communication is viewed as integral to attachment security, a secondary aim was to examine mother–child affective mutuality at 54 months as an intervening interpersonal mechanism between 36-month attachment security and Grade 1 intrapersonal mechanisms.

In accord with the notion of the internal working model as an interpretative filter (e.g., Main et al., 1985), we investigated children's hostile attribution biases as a potential mechanism of attachment – friend linkages. This hypothesis received partial support. Namely, children who experienced greater attachment security with mothers at 36 months tended to engage in more open emotional communication with mothers at 54 months. Open emotional communication at 54 months, in turn, was associated with fewer hostile attributions at Grade 1, which predicted greater teacher-reported friendship quality at Grade 3. Notably, in addition to controlling for maternal education and family income, the association between 54-month affective mutuality and Grade 1 hostile attributions controlled for 54-month hostile attributions, and the association between Grade 1 hostile attributions and Grade 3 friendship quality controlled for Grade 1 language ability and peer competence. As such, our longitudinal, repeated measures strategy provided a stringent test of hostile attributions as an intervening mechanism and lends confidence to the direction of effects posited by the process model. Moreover, these findings are consistent with prior evidence that child – mother attachment security is associated with fewer hostile attributions (Cassidy et al., 1996; Suess et al., 1992) and that hostile attributions are associated with problematic peer functioning (e.g., Dodge et al., 2003; Feldman & Dodge, 1987; Webster-Stratton & Lindsay, 1999). To our knowledge, the current study is the first to examine hostile attributions as a mechanism linking early child – mother attachment with later friendship quality. For the mother model, this indirect effect was nonsignificant, and specifically, Grade 1 hostile attributions were not associated with mother-reported friendship quality, above and beyond language, peer competence, and family demographics. Because vignettes assessing hostile attributions in first grade depicted peer provocations in a school context, Grade 1 hostile attributions may be a more robust predictor of teacher-reported friendship quality. That being said, however, a mother – teacher comparison of this path was nonsignificant.

Surprisingly, attachment security was not associated with 54-month hostile attributions. Likewise, 54-month hostile attributions showed a weak association with Grade 1 hostile attributions and no association with mother- or teacher-reported peer competence. Hostile attributions as assessed at 54 months have been associated in expected ways with teacher-reported social competence and observed child – friend interaction (Webster-Stratton & Lindsay, 1999), yet this prior work assessed bivariate associations only, and participants were predominantly male, at higher risk, and slightly older (68 months, on average). This measure of hostile attribution biases may be less suitable for younger, lower risk children. Also recall that the assessments of hostile attributions varied slightly at the two time points: At 54 months, no picture cues were provided and a forced-choice response format was used, whereas at first grade, line drawings accompanied the vignettes and an open-ended response format was used. Interestingly, in this respect, Cassidy et al. (1996, see study 2) reported attachment-related differences when hostile attributions were assessed via an open-ended question ("Why did the boy/girl . . . ?"), but not a forced-choice question ("Do you think that the boy/girl . . . on purpose or . . . by accident?"). Perhaps children are more likely to rely on their preexisting knowledge base (i.e., latent mental structures) when asked an open-ended question about an actor's intent. A forced-choice question, on the other hand, provides children with socially acceptable or even novel response options and, as such, may mask detection of meaningful individual differences.

A second intervening mechanism of interest was child language ability. For mother and teacher models, child – mother attachment security at 36 months predicted greater language ability at 54 months, which predicted greater peer competence at Grade 1. Peer competence, in turn, predicted greater friendship quality at Grade 3. This indirect effect provides support for language as an intervening mechanism of attachment – friend linkages, but one in which early language ability impacts later friendship quality via more general peer competence. That attachment security predicted language ability above and beyond family demographic variables adds to growing evidence of attachment as a communication system (Bowlby, 1988; Bretherton, 1990; Main et al., 1985) and context for language development (Belsky & Fearon, 2002; van IJzendoorn et al., 1995). The current results also converge with prior work suggesting the importance of language and communicative abilities for children's social skills and friendship quality (e.g., Farmer, 2006; Gottman, 1983). In short, poor language skills during the preschool years may set children on trajectories of problematic relationships with peers. Notably, Grade 1 language ability did not predict mother- or teacher-reported friendship quality above and beyond the other predictors in the model. It may be that language ability as assessed here was not a highly sensitive indicator of the types of language skills that are important for interactions with friends in middle childhood. Researchers should continue to elucidate the role of language as a mechanism of attachment – friend linkages, and adopting more fine-grained assessments of language skills may result in even stronger evidence of language as a critical process linking children's family and peer relationships.

A secondary aim of this study was to assess whether 36-month attachment security was associated indirectly with Grade 1 mechanisms via mother–child affective mutuality at 54 months. Results provided strong support for such processes. Namely, controlling for maternal education and family income, greater child–mother attachment security was associated with more open emotional exchange between 54-month-old children and their mothers. Open emotional exchange, in turn, was associated with fewer hostile attributions in Grade 1 (controlling also for hostile attributions at 54 months), greater language ability in Grade 1 (controlling also for language ability at 54 months), and greater peer competence in Grade 1 (controlling also for hostile attributions and language ability at 54 months). Thus, open emotional communication may be a key interpersonal process through which early attachment security is associated with the development of social-cognitive, linguistic, and social-emotional competencies. We speculate that the "closed" communication style of insecure dyads (especially with regard to negative emotions and events) may result in a hostile attribution bias because the parent explicitly communicates hostile attributions to the child or because the parent does *not* communicate with the child, and the child is left to make sense of the negative emotions or events on his or her own. Similarly, low levels of affective mutuality of insecure dyads may result in fewer opportunities for children to develop language and socioemotional competencies that will be important for later positive interactions with peers.

Examination of child gender as a moderator of the process model indicated that, on the whole, intervening mechanisms operated similarly for boys and girls. For the mother model, however, the indirect effects from attachment security to Grade 1 peer competence and Grade 3 friendship quality via 54-month affective mutuality were significant for boys but not for girls. Further probing indicated that the path from mother–child affective mutuality at 54 months to peer competence at Grade 1 was significant for boys only. Boys, compared with girls, are often socialized to suppress expression of negative emotions (Brody, 1999). Open, mutual exchange of emotions with caregivers, therefore, may be particularly salient for young boys' learning of social-emotional skills that foster harmonious, effective peer interactions.

Strengths of the current research include the large sample size, independent assessments of constructs, and inclusion of maternal education and family income as covariates. These factors yield increased power and reliability to detect indirect effects (see Frazier, Tix, & Barron, 2004). Most importantly, perhaps, the longitudinal design reflected the theoretically guided temporal ordering of constructs in the process model, and in some instances, the repeated assessment of constructs ruled out the possibility that longitudinal associations were due to stability of constructs across time. Thus, greater confidence in conclusions about the proposed direction of effects was achieved by adopting a replicative strategy, which permits an examination of change over time (see Cole & Maxwell, 2003; Hoyle & Robinson, 2004).

Nonetheless, several caveats should be noted. The subsample examined here, although relatively diverse, differed from cases excluded (due to missing data on the Grade 3 friendship outcomes) on demographic and study measures. On the whole, children in the subsample tended to show higher functioning, and it is unclear whether the findings extend to more at-risk populations. Given the potential implications of this process model for intervention, inclusion of clinical populations, in particular, will be important. Also, the amount of variance explained was modest. Future studies should expand on the model presented here to examine additional mechanisms, including emotional regulatory processes that are likely to be shaped by attachment relationships (Cassidy, 1994), integrated into the processing of social information (Lemerise & Arsenio, 2000), and vital to peer functioning (Fabes & Eisenberg, 1992; Parker & Gottman, 1989). Moreover, because the quality of child–friend interaction is influenced by characteristics of both relationship partners (McElwain & Volling, 2002), it is likely that explained variance for friendship quality will increase when social-cognitive and language abilities of both children in the friendship dyad are considered. Finally, the proposed processes may emerge for some groups but not for others. In this report, child gender was examined as a moderator, although overall, the process model functioned similarly for boys and girls. In considering other moderators, investigation of developmental period may be fruitful. Associations between social-cognition and behavioral outcomes become stronger in later childhood and adolescence (e.g., Lansford et al., 2006), and the mechanisms examined here may become more pronounced later in development.

In sum, the current study extends prior work on attachment–friend associations by identifying chains of intervening mechanisms whereby child–mother attachment during the preschool period was associated with children's relationships with friends during middle childhood. Our findings suggest the utility of investigating such processes at the intersection of SIP, language, and mother–child communication about emotions.

Testing an Idealized Dynamic Cascade Model of the Development of Serious Violence in Adolescence

Conduct Problems Prevention Research Group

A dynamic cascade model of development of serious adolescent violence was proposed and tested through prospective inquiry with 754 children (50% male; 43% African American) from 27 schools at 4 geographic sites followed annually from kindergarten through Grade 11 (ages 5–18). Self, parent, teacher, peer, observer, and administrative reports provided data. Partial least squares analyses revealed a cascade of prediction and mediation: An early social context of disadvantage predicts harsh–inconsistent parenting, which predicts social and cognitive deficits, which predicts conduct problem behavior, which predicts elementary school social and academic failure, which predicts parental withdrawal from supervision and monitoring, which predicts deviant peer associations, which ultimately predicts adolescent violence. Findings suggest targets for in-depth inquiry and preventive intervention.

Consensus grows that children who are at high risk for later chronic violence can be identified early in life based on conduct problems (called the early-starter model; Moffitt, 1993; Patterson, Reid, & Dishion, 1992), but the processes are less clear through which minor conduct problems in early life get transformed into costly and serious violent behaviors in adolescence. Numerous variables (classified into domains such as context, parenting, and peer relations; Stouthamer-Loeber, Loeber, Wei, Farrington, & Wikström, 2002) are known to predict adolescent antisocial outcomes, but whether these variables increment the prediction beyond dispositional factors in early life is still under debate (reviewed by Dodge, Coie, & Lynam, 2006). A developmental model of conduct disorder (Conduct Problems Prevention Research Group [CPPRG], 1992) has identified some of the major predictor domains and posits that these domains catalyze early conduct problems into new, more serious, chronically violent behaviors in adolescence. Numerous questions remain about the processes through which early variables operate to produce chronic violence (Dodge & Pettit, 2003). It is not clear how predictor domains relate to each other, whether one domain mediates the impact of another domain, whether some domains account for redundant portions of outcome variance, and whether each domain provides unique increments in predicting violence in adolescence. The major alternate hypothesis (Gottfredson & Hirschi, 1990) is that some

children are born with, or acquire early in life, a disposition for low self-control and become early starters destined for violent outcomes; all other "predictor" variables represent noncausal markers of the child's impact on the world that do not play any incremental role in that child's development. The goals of the current study were to articulate a dynamic cascade model of the development of chronic violence in adolescence that posits incremental roles of numerous life experience factors and to test key hypotheses from the model through a prospective study of children followed from kindergarten through late adolescence. We acknowledge that other plausible cascade models could be tested as well.

Predictors of Adolescent Antisocial Behavior

A large body of empirical evidence has established the predictive validity of at least seven domains of predictors of adolescent conduct problems: early adverse social context, early harsh and inconsistent parenting, lack of social-cognitive and cognitive readiness to begin school, early behavior problems, early school social and academic failure, lack of parental supervision and monitoring in adolescence, and adolescent deviant peer associations (CPPRG, 1992; Dodge, Coie, et al., 2006; Stouthamer-Loeber et al., 2002). Further, it appears that most of these same factors also predict severe interpersonal violence and homicide, the most severe form of conduct problems (Capaldi & Patterson, 1996; Loeber et al., 2005). Other domains are plausible as well, and some of the following domains might be subdivided into more domains, but we offer the following as a heuristic model.

Early adverse social context. Using multilevel analyses of families residing in different neighborhoods in Chicago, Sampson, Raudenbush, and Earls (1997) found large neighborhood variations in youth violent behaviors that are associated with neighborhood structural characteristics. Beyers, Bates, Pettit, and Dodge (2003) used census tract data, and Ingoldsby and Shaw (2002) used self-reports to determine that neighborhood-level scores for the proportions of families characterized by poverty represent a significant risk factor for later individual-level conduct problems. Thus, the neighborhood social context into which a child is born places that child at high (or low) risk for violent behavior many years into the future (Stouthamer-Loeber et al., 2002). None of these scholars proposed that neighborhood context operates directly on a child's behavior; however, the processes through which context exerts influence are not clear.

Adverse context is also indexed by within-family variables during the first 5 years of life. Family socioeconomic status, which is fairly stable across childhood, exerts broad influence across domains from parenting to later conduct problems (McLoyd, 1990). Maternal depression affects the interactions between the mother and child, which may indirectly affect the trajectory of the child's behavioral development. Numerous other community and family context variables are extremely important but are not reviewed here because the focus of this study is on development during the school years.

It must be noted that the paths between adverse contexts and parenting are likely to be reciprocal. Parents with depression and other problems may suffer outcomes that lead them to migrate toward contexts of greater disadvantage.

Early harsh and inconsistent parenting. Most developmental theories propose a major role for the impact of early parenting strategies, especially during discipline encounters with a child (Patterson, 1986; Snyder, Reid, & Patterson, 2003). Harsh discipline in the first 5 years of life has been associated with violent behavior outcomes in adolescence (Lansford et al., 2002), especially when applied inconsistently (Patterson et al., 1992). The lack of warmth between parent and child is also crucial as a predictor (Pettit, Bates, & Dodge, 1997). Caspi et al. (2004) used a monozygotic twin study that controls for genetic differences and found that maternal verbal statements of negative affect about a child (called expressed emotion) predicted children's antisocial behavior problems.

McLoyd (1990) examined the parenting mechanisms through which a context of poverty might exert its impact. She found that poverty increases single African American parents' psychological distress and impairs their social support systems, which, in turn, diminishes their effectiveness and increases their coerciveness toward their children. Sampson and Laub (1994) reanalyzed the Glueck and Glueck (1950) longitudinal data set involving 1,000 Depression-era White families and found that the structural variable of family poverty influenced family processes of harsh discipline, low supervision, and poor parent–child attachment, which, in turn, influenced juvenile delinquency. Family process accounted for two thirds of the effect of poverty on delinquency. Likewise, Dodge, Pettit, and Bates (1994) found that harsh physical discipline by parents accounted for about half of the effect of low socioeconomic status on children's aggressive behavior. Numerous scholars have examined parenting processes during the first 5 years of life in more transactional detail, but the constraints of the design of the current study, which started when children were 5 years old, prohibited detailed analyses of this era.

Lack of school social and cognitive readiness. Children begin formal schooling with large individual differences in social-cognitive and cognitive skills and biases that have been shown to predict antisocial outcomes. Children who are unable to recognize emotions in others (Eisenberg et al., 2004), who demonstrate a bias to attribute hostile intent to peers' intentions (Dodge et al., 1986), and who are relatively poor at social problem solving (Dodge et al., 1986) are at risk for later antisocial behavior. Verbal abilities assessed by intelligence tests have also been found to predict later antisocial behavior (Moffitt & Caspi, 2001).

A growing literature has identified antecedents of social-cognitive skills, particularly in previous parenting. Pollak and Tolley-Schell (2003) found that physically abused children demonstrate selective attention to angry faces and reduced attention to happy faces. Dodge, Bates, and Pettit (1990) identified a pattern of hostile attributional bias and social problem-solving skill deficits that emerged following the experience of harsh discipline from parents. Aber, Gershoff, Ware, and Kotler (2004) found that witnessing family violence around the time of the September 11 disaster predicted children's tendencies to display hostile attributional biases a year later, and Cummings and Davies (2002) have argued that emotion dysregulation is the process that mediates the relation between witnessing marital conflict and later child aggression.

Early behavior problems. The continuity of externalizing behavior problems across development is one of the most well-documented findings in longitudinal inquiry in social development (Dodge, Coie, et al., 2006). Although the form of antisocial behavior may change from disobedience and oppositional behavior in early childhood to violence and crime in adolescence, continuity in the rank ordering of individual differences is the basis for the early-starter model (Moffitt, 1993). It is imperative that a cascade model describes the processes that transform antisocial behavior from one form to another and highlights factors that deflect this trajectory.

School social and academic failure. Deficits in school readiness skills are hypothesized to lead to school failure in peer relations and academic performance, which, in turn, have been linked to later antisocial outcomes. Dodge et al. (2003) found that the experience of social rejection by peers leads to growth in antisocial behavior across elementary school. Academic failure, indexed by grade retention, placement into special education, and failing test scores, represents another predictor of antisocial outcomes (Hinshaw, 1992; Moffitt, Gabrielli, Mednick, & Schulsinger, 1981). Meta-analyses suggest that kindergarten and early grade retention has long-term detrimental effects on behavior outcomes, in spite of temporary academic benefits (Holmes, 1989).

Lack of parental monitoring. As children move into adolescence, the tasks of parenting change, as do the parenting predictors of antisocial outcomes. Parents' lack of monitoring of their child's whereabouts, failure to supervise behavior and time allocation, and lack of engagement with the youth in schooling all have been associated with antisocial outcomes in adolescence (Dishion & McMahon, 1998). Monitoring is especially important as a protective factor among youth who reside in a social context of danger and risk (Pettit, Bates, Dodge, & Meece, 1999). Dishion, Nelson, and Bullock (2004) used video records of parent–adolescent interaction to determine that directly observed parental disengagement predicted growth in the youth's associations with deviant peers and delinquent outcomes. Hill et al. (2004) found that lack of parental involvement in school during the middle school years predicted a youth's later maladjustment.

Although individual differences in parents' lack of monitoring and engagement have been found to increment the prediction of antisocial outcomes beyond the levels that anteceded monitoring, it is plausible that these patterns are at least partly elicited by the child. Parent–child conflict may well be stressful, and monitoring by parents might intensify conflict when the parent discovers misbehavior. Thus, early school problems might well lead to lower levels of parental monitoring in adolescence (Stattin & Kerr, 2000). Laird, Pettit, Bates, and Dodge (2003) found evidence to support a reciprocal-influence model of growth in youth antisocial behavior and parental withdrawal of monitoring over time. Evidence by Larzelere and Patterson (1990) indicates that parent management practices in sixth grade, including monitoring, mediated the impact of prior family socioeconomic status on antisocial behavior measured in seventh grade from police records and self-report. Thus, parents' monitoring activities may well grow out of prior contexts but appear to increment and mediate later outcomes.

Deviant peer associations. The final domain of predictors of adolescent violent behavior is association with deviant peers. This factor has received a wide variety of empirical support as a proximal predictor of adolescent deviant behavior. Patterson et al. (1992) found that involvement with deviant peers in Grade 6 (measured by parent, peer, and self descriptions) predicted subsequent delinquency even controlling for prior antisocial behavior. Simons, Wu, Conger, and Lorenz (1994) also found that association with deviant peers predicted subsequent arrests. Laird, Jordan, Dodge, Pettit, and Bates (2001) found that deviant peer associations predicted growth in antisocial behavior, and Keenan, Loeber, Zhang, Stouthamer-Loeber, and Van Kammen (1995) found that in the Pittsburgh Youth Study authority conflict was twice as likely to occur among those disruptive boys who had truant or disobedient best friends as among those who did not. Two important features of this study were the fact that onset was the dependent variable, thus controlling for previous disruptive behavior, and the fact that peer influence was tested within a specific type of antisocial activity as a way of examining the extent to which peers truly were models of deviant behavior.

The antecedents of deviant peer associations are varied, but low parental monitoring has been implicated in several studies. Snyder, Dishion, and Patterson (1986) found a strong path relation between low parental monitoring and increases in deviant peer associations. Simons et al. (1994) found that problems in parental discipline practices (including poor monitoring) predicted increased deviant peer associations and later criminal arrests. Thus, it is plausible that the effect of the lack of parental monitoring on antisocial outcomes is mediated through enhanced deviant peer associations.

A Dynamic Cascade Model of Development

The aforementioned body of empirical evidence suggests that predictor domains for adolescent violence may intercorrelate, as in Figure 1. Reducing the paths in this figure to the minimum necessary uniquely contributing components is one goal of efficient longitudinal modeling. We propose the dynamic cascade model represented in Figure 2 to describe this developmental process. We recognize that alternate cascade models could hold as well.

This model begins with a child's birth into an adverse social context, characterized by high neighborhood disadvantage and low neighborhood access to social services. It is hypothesized that this context places a child at risk for a variety of problem outcomes throughout life, including chronic antisocial behavior in adolescence. Although a comprehensive model would also include the domain of prenatal experience and temperament, which act as biologically based dispositions to act impulsively and without delay of gratification, the current empirical study began with children at age 5 and could not unambiguously measure this domain. Thus, it is not discussed further.

It is hypothesized that the domain of adverse social context operates on adolescence violence primarily indirectly through impact on life circumstances across childhood, especially early parenting. An adverse social context increases family stress and the rate of maternal depression that makes it more difficult to parent effectively, especially during discipline events. It is hypothesized that harsh and inconsistent discipline practices and lack of parental warmth predict adolescent violence, partially mediate the impact of an adverse social context on later violence outcomes, and increment the prediction of violence outcomes beyond context predictors.

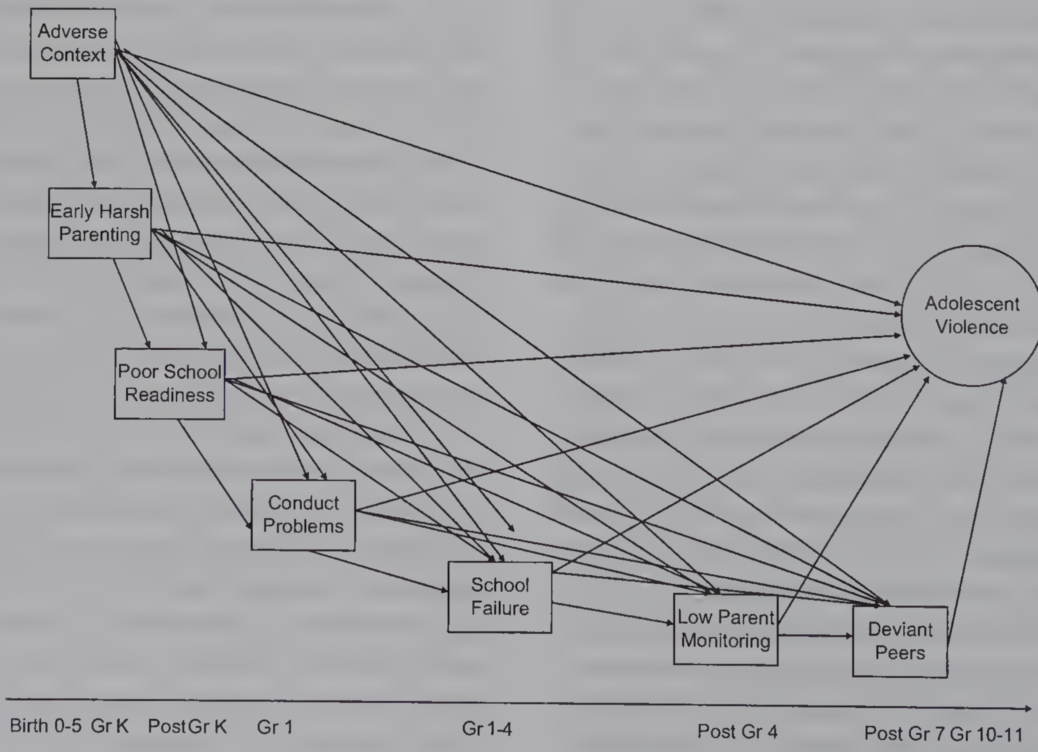

Figure 1. Hypothesized correlations among domains in the development of violence.

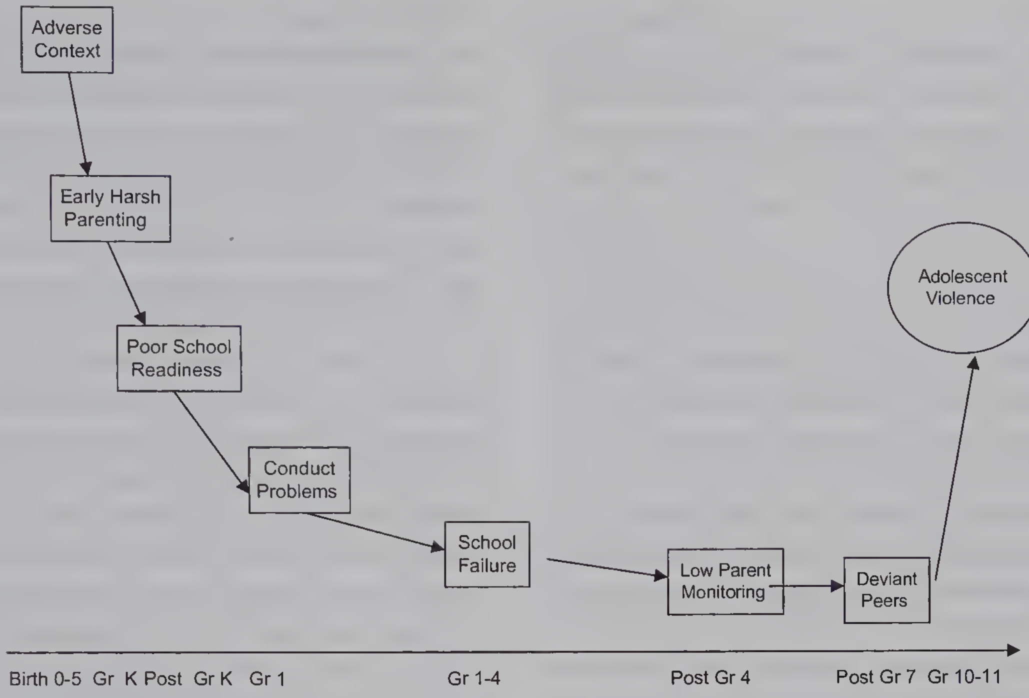

Figure 2. Hypothesized dynamic cascade model of the development of violent behavior.

But how does the impact of early parenting practices operate? These discipline practices are hypothesized to reduce the child's opportunities for learning self-regulatory, social-cognitive, and cognitive skills and attitudes that might be called school readiness skills. Deficits in these skills, in turn, are hypothesized to predict adolescent violence, to mediate the impact of parenting practices on violence outcomes, and to increment the prediction of violence outcomes.

How do school readiness skill deficits, in a context of poverty and harsh and inconsistent parenting, lead to adolescent violence? It is hypothesized that these deficits increase the probability that a child will experience failure in peer relations and academic performance. School social and academic failure, in turn, is hypothesized to predict adolescent violence outcomes, to mediate the impact of school readiness skills deficits, and to increment the prediction of these outcomes beyond the skill deficits themselves.

School failure operates, in turn, partially through its reciprocal impact on the parent–child relationship. School and peer conflict make parenting an even more difficult task that requires intensified monitoring and supervision of a child, enhanced parent–child communication, and enhanced parent involvement at school; however, it is hypothesized that these school problems have a paradoxical effect on lowering parental monitoring, supervision, communication, and involvement, in order to reduce conflict or because the parent has begun to give up on exerting an impact on the child. Low parental monitoring is hypothesized to predict adolescent violence outcomes, to mediate partially the impact of school failure on these outcomes, and to increment the prediction of these outcomes beyond school failure.

Finally, a major product of low parental monitoring and school involvement is the youth's tendency to associate with deviant peers. This pattern is hypothesized to have a proximal impact on potentiating adolescent violent behavior, to mediate partially the impact of low parental monitoring on violent behavior, and to increment the prediction beyond low parental monitoring.

The proposed model is a cascade because the six predictor domains are ordered in temporal sequence with each successive stage posited as a partial product of previous stages but also providing added impact on the process (CPPRG, 1992). It is a dynamic model consistent with that posed by Granic and Patterson (2006) because the steps are not hypothesized to operate only in linear ways at regular time intervals. The model is one in which a high-risk child traverses a deepening stream across development toward a violent outcome, with each stage of development being predicted partially from previous events and providing growing inevitability toward the violent outcome, but also offering a new opportunity to begin a different tributary toward a nonviolent outcome.

Testing the Model

Beyond identifying the major domains of predictors of antisocial behavior and the specific variables within domains, the developmentalist's task is to understand how these processes operate in tandem to produce antisocial outcomes. Rutter and Garmezy

(1983) pioneered the cumulative risk model that posits that prediction is strongest simply by summing the number of risk factors, consistent with the idea that these domains will provide unique increments in predicting youth outcomes. Others have found evidence to support this model (Greenberg, Lengua, Coie, Pinderhughes, & CPPRG, 1999; Sameroff, Bartko, Baldwin, & Baldwin, 1988). However, such a model does not address the intercorrelations among predictors or begin to explain processes through which the risk factors operate. The proposed dynamic cascade model posits that a domain operates on antisocial outcomes by directly influencing the next domain in the hypothesized temporal sequence. This next domain both mediates the impact of the prior domain and catalyzes further antisocial development in an incremental manner.

Although the full dynamic cascade model posits many hypotheses, the following 21 hypotheses were tested in the current study:

> H1a to H1f: Predictor domain x will significantly predict the adolescent violence outcome.
>
> H2a to H2e: Predictor domain x will predict predictor domain $x + 1$.
>
> H3a to H3e: Predictor domain $x + 1$ will mediate (either fully or at least partially) the relation between the previous predictor domain x and the adolescent violent outcome.
>
> H4a to H4e: Predictor domain x will significantly increment the prediction of the adolescent violence outcome beyond the prediction afforded by predictor domain $x - 1$.

Our ability to test hypotheses of the proposed model empirically is limited by the sample being studied, the variables that we measure, and the methods that we apply in analysis. The current study was designed to test key features of this model in a diverse sample of boys and girls from four geographic sites followed from kindergarten through late adolescence. The sample included both the normative and high-risk control samples of the Fast Track Study (CPPRG, 1992), a randomized controlled trial of the efficacy of a preventive intervention designed following the premises of the proposed model. We oversampled, and appropriately weighted, early-starting high-risk children by including the high-risk control children in the randomized trial. No child who was assigned to receive intervention was included in the current study.

The outcome variable was an index of serious violent behaviors in Grades 10 and 11 of high school. This construct is inherently skewed, with only about one fourth of the sample receiving scores greater than 0. Variation above 0 was considered meaningful, however.

The proposed model does not stipulate that variables within a predictor domain represent indicators of a single latent construct defined by that domain. Rather, within-domain variables represent a collection of manifest factors that are conceptually related, measured at roughly the same time point, and possibly (though not necessarily) correlated with each other. They are aggregated in a weighted index, similar to an index of adverse life events or stressors, rather than a latent trait. Thus, we required a data-analytic method that would preserve these characteristics of each predictor domain but yield a single factor for simplicity of hypothesis testing. We chose to compute partial least squares (PLS) variates for each domain and test hypotheses through model contrasts and significance testing by a bootstrap method.

Impact of Gender

Because males are more likely than females to become seriously violent and because of obvious biological and socialization differences across genders, any comprehensive developmental model must contend with the question of whether developmental pathways vary for males and females. Gorman-Smith and Loeber (2005) found similarity with the prior empirical literature on males in the predictors of violence that emerged in their all-female sample. The current sample includes both genders, with sufficient numbers of high-risk females to test major hypotheses in each gender. With the predictor variables studied here, we had no reason to hypothesize gender-specific pathways. Nonetheless, the gender interaction hypothesis was tested by contrasting models that allowed paths to differ (or not) for each gender.

Variation by Level of Initial Risk

Although it is often assumed that predictor variable operates similarly across the range of risk in a population, recent reports of interaction effects between level of genetic or biological risk and environmental risk in predicting antisocial outcomes suggest that the impact of environmental variables might differ for children at high and low early risk. For example, Lynam et al. (2000) found that adverse neighborhood context exerted a stronger effect on antisocial outcomes among impulsive adolescents than nonimpulsive adolescents. Lengua, Wolchik, Sandler, and West (2000) found that maternal inconsistent discipline had a stronger impact on externalizing behavior among impulsive toddlers than among nonimpulsive toddlers. Dodge et al. (2003) found that peer social rejection had a stronger effect on increasing aggressive behavior outcomes among children who had been above the median in aggression initially than children below the median.

Participants in the current study included a community sample of children who represented the normative distribution of risk for antisocial outcomes and a sample of high-risk children selected on the basis of early conduct problems. These samples afforded the opportunity to test whether developmental models varied across risk groups.

Method

Participants

Participants came from the control schools of a longitudinal, multisite investigation of the development and prevention of conduct problems in children, the Fast Track Project (CPPRG, 1992). At each of four sites (Durham, NC; Nashville, TN; Seattle, WA; and central Pennsylvania), high-risk schools were selected and randomly assigned to intervention or control conditions. From among the control schools ($n = 27$), teachers completed ratings of child disruptive behavior to identify a within-site stratified sample of about 10 children within each decile of behavior problems. Across the four sites, 387 children were selected to represent the normative population of these schools. In addition, high-risk children were oversampled to measure finer gradations of high risk. A multistage, multi-informant screening process identified three annual cohorts of kindergartners with highest disruptive behavior scores, yielding an additional n of 367, bringing the total number of participants to 754 (see Lochman & CPPRG, 1995, for further details). Of the normative sample, 35% came from single-parent families, 23% of mothers had not graduated from high school, 50% were male, and 43% were African American. Although the high-risk subsample included higher proportions of each of these characteristics, weighting was used in all analyses to reflect the oversampling of high-risk children.

Procedures

Beginning in kindergarten and lasting through Grade 11, annual measurements were collected from multiple sources that included the teacher, the peer group, administrative school records, the mother, the child, and interviewer ratings. Teacher, peer, and administrative record measures were collected in the spring, and mother, child, and interviewer measures were collected in the following summer.

Measures

The following measures used in the current study are described in detail at www.fasttrackproject.org. All measures were scored so that higher scores are more negative. Prior to administration, interviewers received extensive training, including reading manuals, observing videotapes, participating in guided practice and role plays, observing trainers conduct home visits, completing pilot home visits themselves, and having trainers supervise home visits until the interviewers achieved a minimum of 70% agreement on all ratings. During the spring prior to summer home visits, trainers from each study site attended multiday teaching sessions designed to ensure project-wide standardization. During the summer data collection periods, these trainers participated in regular conference calls to contain site-specific drift (Pinderhughes, Nix, Foster, Jones, & CPPRG, 2001).

Adverse social context. Four variables indexed the child's early adverse social context. First, the interviewer who visited the child's home in the summer after kindergarten completed a four-item assessment of the *neighborhood danger* (*1a*) immediately after the visit. The scale summed responses regarding the safety of the dwelling, the street, and the neighborhood, and the disruptiveness of noise, on 4-point scales ($\alpha = .83$, scale of 4–16). Second, during the initial interview in kindergarten, the mother was asked to respond to each of two items on 10-point scales regarding her satisfaction with neighborhood services for transportation and education. These items were summed to yield a score for *lack of neighborhood services* (*1b*) ($\alpha = .41$, scale of 2–20). Third, during the interview the parent reported the education level and occupation of the child's biological father and biological mother. Following Hollingshead (1975), these four responses were scored and combined to form a single score for *family socioeconomic status* (*1c*), ranging from 8 to 66 ($M = 27.8$, $SD = 13$). Fourth, during the interview after Grade 1, the mother completed the Center for Epidemiological Studies Depression Scale (Radloff, 1977). Each of 20 items was rated on a scale of 0–3, yielding a sum score for *maternal depression* (*1d*) ($\alpha = .89$, scale of 0–60). It was first administered after Grade 1, and it was inferred that it represented a stable construct from early life.

Early harsh and inconsistent parenting. Five scores indexed early harsh parenting. During the first home interview following kindergarten, the interviewer presented the parent with six hypothetical vignettes taken from Dodge et al. (1990), each depicting a parent–child interaction in which the child misbehaves. The parent responded with the behavioral reaction that she would give, which was scored for physical punishment (0 = *not mentioned*, 1 = *mentioned*). The items were averaged to yield a score for *harsh discipline—vignette* (2*a*) (α = .60, scale of 0–1). During the same interview, the parent completed the Conflict Tactics Scale (CTS; Straus, 1979), which asks the parent to report on a 7-point scale the frequency with which she displays various discipline tactic toward the child. A scale of *corporal punishment—CTS* (2*b*) was derived as the mean of three items (spank, spank with object, and hit; α = .79, scale of 0–6). During the same interview, the interviewer engaged in an open-ended interview with the parent about discipline of the child, following the protocol defined by Dodge et al. Following a discussion about how the parent typically disciplined the child, including a discussion of the most severe episodes, the interviewer made a private 5-point scale rating of the harshness of the discipline received by the child, called *harsh discipline—interviewer rating* (2*c*). This measure was adapted from Lansford, Deater-Deckard, Dodge, Bates, and Pettit (2004), who conducted independent coder agreement checks on 56 randomly selected mothers and found that intercoder agreement was acceptable (r = .80, p < .001).

During the same home visit, the parent and child were asked to complete four interaction tasks taken from Eyberg (1974): a child's game, a parent's game, a Lego task, and cleanup. Interviewers were trained in the administration of this task and coding of behaviors by a supervisor with prior experience with this measure or someone trained by that person until they reached acceptable agreement. This well-validated measure has been used by one of the current study authors (Crnic & Greenberg, 1990) in numerous studies. The interviewer observed the interaction and immediately made 5-point ratings, taken from Crnic and Greenberg (1990). Six items were averaged to yield a scale of *lack of parental warmth—observed* (2*d*) (e.g., parent's apparent gratification, sensitivity, and involvement during each segment; α = .90, scale of 1–5). Finally, the parent completed the Parent Questionnaire (Strayhorn & Weidman, 1988), which included seven items asking the parent to report (using a 5-point scale) her use of appropriate and consistent discipline strategies (e.g., "what percent of time do you follow up on your commands?" "How much does your discipline vary with your mood?"). These responses were averaged to yield a score for *inconsistent discipline—parent report* (2*e*) (α = .67, scale of 1–5).

School social and cognitive readiness. Five variables indexed social and cognitive readiness. During the first interview with the child, the child was administered the standardized 57-item Woodcock–Johnson Test, which yielded a score for *Woodcock–Johnson Letter/Word Identification* (3*a*) (α = .88, scale of 0–57). The child also completed the Wechsler Intelligence Scale for Children vocabulary subtest, which yielded a scaled score for *vocabulary skill* (3*b*), which has a nationally normed mean of 10 and an *SD* of 3. The child completed the Social Problem Solving Test, adapted from Dodge et al. (1990), in which the child was presented with each of eight drawings depicting social dilemmas (e.g., "A peer is playing with your bicycle and you want it back; how could you get it back?") and was asked how he or she could solve the dilemma. Responses were recorded verbatim and categorized later as competent or not. The proportion of responses across vignettes categorized as competent constituted a score for *competent social problem solving* (3*c*) (α = .66, scale of 0–1). The child also completed the Home Interview With Child measure (Dodge et al., 1990) which assesses hostile attributional biases. The child responded to each of eight drawings depicting hypothetical provocation vignettes in which the child imagined being provoked by a peer (e.g., "A peer bumps into you.") by stating whether the peer had likely acted with benign or hostile intent. The proportion of times that a child responded with hostile intent was scored as a measure of *hostile attributional bias* (3*d*) (α = .78, scale of 0–1). The child also completed the Emotion Recognition Questionnaire, adapted from Ribordy, Camras, Stefani, and Spaccarelli (1988), which consists of 16 vignettes depicting a child experiencing an emotion (happy, sad, fear, angry). The child was asked to identify the emotion being depicted. The number of correct responses was scored as a measure of *emotion recognition skill* (3*e*) (α = .65, scale of 0–16).

Child externalizing problems. The child's externalizing behavior problems were assessed using the Child Behavior Checklist (Achenbach, 1991) with parent and teacher reports collected at the end of kindergarten. The highly reliable *T* scores for the 50-item externalizing problems scale were log transformed to produce scores for *child externalizing problems—teacher report* (4*a*) and *child externalizing problems—parent report* (4*b*).

School social and academic failure. Five scores indexed elementary school social and academic failure.

During the spring of Grade 2, all consenting peers (at least 75% of parents in each classroom for which scores are tabulated provided written informed consent) in a child's classroom were asked to complete a sociometric interview in which they were asked to nominate children whom they like and whom they dislike. The numbers of nominations received in each category were summed, standardized within classroom, and differenced. A score for *peer social rejection* (*5a*) (0 = *not rejected*, 1 = *rejected*) was computed following the formula by Coie, Dodge, and Coppotelli (1982). *Grade retention* (*5b*) was scored from the child's official school records in Grades 2, 3, and 4 as 0 (*never retained*) or 1 (*ever retained in grade*). Placement into *special education* (*5c*) was scored from the same records as 0 (*never*) or 1 (*ever*). Core subject *failing grades* (*5d*) was scored from the same records as whether the child had ever received a failing grade in a core subject, scored as 0 (*never failed*) or 1 (*ever failed*). Finally, *academic competency problems* (*5e*) was scored based on the child's performance on the three scales of the 158-item Woodcock–Johnson Test in Grade 4 (α = .87). A child was given a score of 0 if he or she received a score lower than 1.5 *SD*s below the sample mean on any of three subtests (passage comprehension, letter/word identification, and calculation), and 1 otherwise.

Adolescent parental monitoring. Six scales were collected from parents and children during or after Grade 4 to assess parental monitoring and supervision of the child. The first scale, called *parental supervision—child report* (*6a*) was derived as the mean of five items of the Supervision/Involvement Scale of the Pittsburgh Youth Study (Loeber, Farrington, Stouthamer-Loeber, & von Kammen, 1998). For each item, the youth responded no or yes (e.g., "Does your parent know who you are with when you are away from home?"; α = .62, scale of 1–5). The second scale, called *parental supervision—parent report* (*6b*), was derived from the same source and asked parents the same items from their perspective (α = .55, scale of 1–5). The third scale, adapted from the Revised Parent–Adolescent Communication Form of the Pittsburgh Youth Study (see Loeber et al., 1998), includes five items (coded on a 5-point scale from *almost never* to *almost always*) that assess a child's perceptions of his or her *parent openness to communication* (*6c*) (e.g., "My parent is a good listener."; α = .56, scale of 1–5). The fourth scale was adapted from the same source as the third scale and includes five items that assess the parent's perceptions of his or her *parental communication with child* (*6d*) (e.g., "I discuss my child's problems with him or her.") (α = .73, scale of 1–5). The fifth scale was adapted from the same source as the third scale and includes five items that assess the child's perceptions of his or her *communication with parents* (*6e*) (e.g., "I discuss my problems with my parents"; α = .75, scale of 1–5). The sixth scale, developed for this study, is the *parent involvement in school* (*6f*), for which the teacher answered twenty-one 5-point-scale items about the parent's contact, involvement, and comfort with the teacher (α = .91, scale of 0–4).

Adolescent deviant peer associations. Two scales indexed this domain after Grade 7. For the first scale, the parent completed the Parent Report on Child's Close Friends, consisting of 10 questions developed for the current study that assessed *deviant peer associations—parent report* (*7a*) (α = .87, scale of 4–40), centered around three main topics: the child's best friend, the child's second best friend, and the child's close friends. For each topic, the parent was asked to respond on a 4-point scale to these questions (a) Does this friend get into trouble with teachers, the police, or other adults? (b) Does this friend do things you disapprove of? (c) Are you concerned about the negative influence this friend has on your child? The tenth 5-point scale question asked parents, "How much does your son/daughter hang around with kids who get into trouble?" For the second scale, the youth completed the Self-Report of Close Friends, which included five items developed for the Seattle Social Development Project (O'Donnell, Hawkins, & Abbott, 1995) that measured *deviant peer associations—youth report* (*7b*) (α = .82, scale of 1–4). The youth was asked to identify two best friends and answer questions about behaviors by the friend including delinquency, substance use, school motivation, and parental attitudes toward the friend.

Adolescent violent behavior. In the summers after Grades 10 and 11, the youth and parent reported the youth's violent behavior in the past 12 months. Six youth-report items each year were taken from Huizinga and Elliot's (1987) Self-Report of Delinquency, and eight items each year were taken from the Guns and Gangs instrument developed for this study (CPPRG, 1999). Two parent-report items each year were taken from the Parent Report of Delinquency (CPPRG, 1999). The 32 items (listed in Table 1) were each scored as 0 if *no* and 1 if *yes*, with the sum indexing *serious interpersonal violence* (*8*) (α = .49, scale of 0–16).

Modeling Strategy

We developed a two-stage modeling process to accommodate the distinctive characteristics of our measurement model and to evaluate the structural model properly. First, we applied PLS (Chin, 1995) modeling to develop the measurement model for

Table 1
Variables Used in Index of Adolescent Violent Behavior

No.	Variable	Source	Wording
	Self-report of delinquency		
1	C11AD26a	Self	In the past year, have you attacked anyone with the intent to hurt or kill?
2	C11AD27a	Self	In the past year, have you hit someone with the idea of hurting them?
3	C11AD28a	Self	In the past year, have you used a weapon to get money from people?
4	C11AD29a	Self	In the past year, have you thrown objects at people?
5	C11AD30a	Self	In the past year, have you been involved in any gang fights?
6	C11AD32a	Self	In the past year, have you had sex with someone against their will?
	Guns and gangs		
7	C11AW2d	Self	In the past 12 months, have you ever pulled a small pocket knife on another person?
8	C11AW2e	Self	In the past 12 months, have you ever hurt someone with a small pocket knife?
9	C11AW3d	Self	In the past 12 months, have you ever pulled a switchblade, razor, or other big knife on another person?
10	C11AW3e	Self	In the past 12 months, have you ever hurt someone with a switchblade, razor, or other big knife?
11	C11AW4e	Self	Guns in your home that your parents own for their protection or for hunting—In the past 12 months, have you ever pulled it on another person?
12	C11AW4f	Self	Guns in your home that your parents own for their protection or for hunting—In the past 12 months, have you ever hurt some one with it?
13	C11AW5d	Self	A gun that is not for hunting—In the past 12 months, have you ever pulled one on another person?
14	C11AW5e	Self	A gun that is not for hunting—In the past 12 months, have you ever hurt someone with it?
	Parents' report of delinquency		
15	P11AG11	Parent	How often has your child attacked someone with a weapon with the idea of seriously hurting them?
16	P11AG16	Parent	How often has your child carried a weapon?

predictor constructs. PLS modeling as applied here is superficially similar to confirmatory factor analysis (CFA) but uses an alternative estimation technique (vs. maximum likelihood) that has its own advantages and disadvantages. In PLS, summary variables are modeled with formative indicators, versus reflective indicators usual for latent variables in CFA. It is also possible to model variables with formative indicators in structural equation modeling (SEM), but the requirements for model identification are much more stringent. Reflective approaches are appropriate when component variables are presumed to be indicators of a single latent construct (such as a trait), whereas formative approaches make no such assumption (such as indicators of a total stress index or life events index). The formative indicator approach involves each summary variable being modeled as a linear composite of its components, as in a principal components analysis, rather than being a source of common variance among a factor's indicators. The key difference between a PLS analysis and a principal components analysis is that in the latter, the composites are constructed to maximize the variance of the indicators accounted for by the component, whereas in PLS, the indicators for each composite are weighted to maximize the strength of the relations among the PLS variates (similar to a canonical correlation), resulting in the best possible prediction of the downstream variate. Rather than assume equal weights for all indicators of a scale, the PLS algorithm allows each indicator to vary in how much it contributes to the composite score. Thus, indicators with weaker relations to indicators and the construct are given lower weightings. In this sense, PLS is preferable to techniques such as regression that assume error-free measurement (Lohmoller, 1989; Wold, 1982).

Once the PLS weights for the predictors were estimated, we tested our hypotheses about the relations among these blocks of variables in an SEM framework, using standardized scores for the variates to ease interpretation of results. Given our intent in predicting the interpersonal violence outcome, we estimated seven separate PLS models. In each model, one time block of predictors (social context, early parenting, etc.) formed the PLS variate, weighted to maximize the prediction of the violence score. An alternative strategy would have been to estimate weights for all seven variates in a single PLS model; however, the PLS algorithm would have then also worked to maximize prediction among the seven predictor variates, at the cost of maximal prediction of interpersonal violence. We then retained the individual scores. Weights for the scores are shown in Table 2.

Results

Descriptive Statistics and Treatment of Missing Data

Descriptive statistics (means, standard deviations, missing data rates, and correlations with the adolescent violence score) for the manifest variables used in the analysis, incorporating the sample weights reflecting the oversampling of higher risk students, are shown in Table 2. We conducted our PLS modeling in SAS Version 9.1.3 (SAS Institute, 2004), which includes the option to accommodate missing data by estimating

Table 2

Means, Standard Deviations, Percent Missing, Partial Least Squares (PLS) Variate Weights, and Correlations With Violence Outcome

Variable	*M*	*SD*	% missing	PLS	*r* w/viol
Early adverse social context					
1a. Neighborhood danger (age 0–5)	8.47	2.37	4.1	.080	.08
1b. Lack of neighborhood services (age 0–5)	14.92	4.35	0.4	.144	.25*

values for the scores through the EM algorithm. One important component of this modeling is estimation of the standard error in the context of missing data estimation, which we completed in Mplus Version 4.1 (Muthén & Muthén, 2006), using its facility for the bootstrap, and accommodating the sample weights. Standard errors for this and all further analysis were based on simple bootstrap of 500 samples. The combination of the EM algorithm and bootstrapped standard errors adjusts for missing data under the assumption of missing at random (MAR). The MAR assumption is that all relations between the probability of a response being missing and the true value of that response are accounted for by other observed variables in the model. The MAR assumption is not logically testable; however, analyzing data that do not meet this assumption by MAR methods has been shown to be preferable to ad hoc approaches to missing data such as listwise deletion (Graham, Hofer, & MacKinnon, 1996). We estimated the correlations among the PLS variates (and the interpersonal violence score) in Mplus v.4.1 (Muthén & Muthén, 2006). Correlations appear in Table 3.

We then tested the cascade nature of the relations among PLS variates. It was hypothesized that each variate would cascade to predict the next variate immediately downstream. We tested each variate (except the first social context) as a mediator of the relation between the immediately prior variate and the ultimate outcome, interpersonal violence. Mediation was tested by the comparison of the product of the two relevant coefficients (prior to central, central to posterior) to its bootstrapped standard error, using significance thresholds determined and recommended by MacKinnon, Lockwood, Hoffman, West, and Sheets (2002, 2006). The coefficient is unbiased in testing the statistical significance of at least partial mediation. Whether mediation is full or partial is tested by the coefficient for the predictor variate in predicting the outcome net of the effect of the mediator. All relevant statistics appear in Table 4.

Results of Hypothesis Tests

Adverse social context. Hypothesis H1a was supported: Adverse social context was a significant predictor of adolescent violence, $r = .30$. Hypothesis H2a was supported: Adverse social context was

Table 3

Correlations Among Partial Least Squares Variates and Violence

	Adverse context	Early harsh parenting	Social/cognitive deficits	Externalizing behavior	Social/academic failure	Low monitoring	Deviant peer

a significant predictor of harsh and inconsistent early parenting, $r = .42$.

Harsh and inconsistent early parenting. Hypothesis H1b was supported: Harsh and inconsistent early parenting was a significant predictor of adolescent violence, $r = .20$. Hypothesis H2b was supported: Harsh early parenting was a significant predictor of lack of school readiness, $r = .33$. Hypothesis H3a was supported: Harsh and inconsistent early parenting partially mediated the prediction of adolescent violence from adverse social context, *Est./SE* = 2.21. Hypothesis H4a was supported: Harsh and inconsistent early parenting significantly incrementally predicted adolescent violence, controlling for adverse social context, $b = .099$.

Lack of school social and cognitive readiness. Hypothesis H1c was supported: Lack of school readiness was a significant predictor of adolescent violence, $r = .20$. Hypothesis H2c was supported: Lack of school readiness was a significant predictor of early child externalizing problems, $r = .12$. Hypothesis H3b was supported: Lack of school readiness partially mediated the prediction of adolescent violence from harsh early parenting, *Est./SE* = 3.75. Hypothesis H4b was supported: Lack of school readiness significantly incrementally predicted adolescent violence, controlling for harsh and inconsistent early parenting, $b = .147$.

Early child externalizing problems. Hypothesis H1d was supported: Early externalizing problems were a significant predictor of adolescent violence, $r = .25$. Hypothesis H2d was supported: Early externalizing problems were a significant predictor of school failure, $r = .18$. Hypothesis H3c was supported: Early externalizing problems partially mediated the prediction of adolescent violence from lack of school readiness, *Est./SE* = 2.01. Hypothesis H4c was supported: Early externalizing problems significantly incrementally predicted adolescent violence, controlling for lack of school social and cognitive readiness, $b = .213$.

School social and academic failure. Hypothesis H1e was supported: School failure was a significant predictor of adolescent violence, $r = .18$. Hypothesis H2e was supported: School failure was a significant predictor of lack of parental monitoring, $r = .22$. Hypothesis H3d was supported: School failure partially mediated the prediction of adolescent violence from early externalizing problems, *Est./SE* = 2.61. Hypothesis H4d was supported: School failure significantly incrementally predicted adolescent violence, controlling for childhood externalizing behavior problems, $b = .158$.

Lack of parental monitoring. Hypothesis H1f was supported: Lack of parental monitoring was a significant predictor of adolescent violence, $r = .16$. Hypothesis H2f was supported: Lack of parental monitoring was a significant predictor of deviant peer involvement, $r = .20$. Hypothesis H3e was supported: Lack of parental monitoring partially mediated the prediction of adolescent violence from school failure, *Est./SE* = 2.53. Hypothesis H4e was supported: Lack of parental monitoring significantly incrementally predicted adolescent violence, controlling for school failure, $b = .139$.

Deviant peer associations. Hypothesis H1g was supported: Deviant peer involvement was a significant predictor of adolescent violence, $r = .26$. Hypothesis H3f was supported: Deviant peer involvement partially mediated the prediction of adolescent violence from lack of parental monitoring, *Est./SE* = 2.30. Hypothesis H4f was supported: Deviant peer involvement significantly incrementally predicted adolescent violence, controlling for lack of parental monitoring, $b = .272$.

Tests of Full Model

The next stage of analysis was to construct a full path model showing the prediction of each construct from all prior constructs. In this model, estimated using Mplus Version 4.2 (Muthén & Muthén, 2006), each variate was incorporated predicting each subsequent variate and interpersonal violence. Parameter estimates and bootstrapped standard errors are shown in Table 5. This overall model was saturated and thus not testable. Tests of paths, however, indicated that each step was significantly predicted from the previous steps taken together, and the best prediction of violence came from multiple steps.

Gender Differences in Means and Developmental Paths

Simple *t* tests indicated that males received significantly higher raw adolescent violence mean scores than females ($p < .001$). Males and females did not differ in the adversity of their home context, in early parenting, or in early externalizing problems scores (only because *T* scores that standardize within gender were used), but males received significantly higher scores than females for lack of school social and cognitive readiness ($p < .02$), school social and academic failure ($p < .001$), lack of parental monitoring and communication ($p < .02$), and deviant peer associations ($p < .001$).

To test the hypothesis that developmental paths would differ across gender groups, the full model was contrasted with a model in which path coefficients were allowed to vary across male and female groups. Loosening the constraint that the paths are identical did

Table 5

Prediction Between Partial Least Squares Variates and Violence in Full Model

	Step 1: Adverse context	Step 2: Early harsh parenting	Step 3: Social/cognitive readiness	Step 4: Early externalizing problems	Step 5: School social/academic failure	Step 6: Adolescent parental monitoring	Step 7: Deviant peer association
Step 2:Eearly harsh parenting	.384 (.040)*						
Step 3: Social/cognitive readiness	.262 (.048)*	.264 (.049)*					
Step 4:Eearly externalizing problems	.294 (.051)*	.331 (.055)*	−.062 (.046)				
Step 5: School social/academic failure	.042 (.045)	.159 (.056)*	.191 (.044)*	.065 (.037)			
Step 6: Adolescent parental monitoring	.079 (.047)	.216 (.053)*	.108 (.041)*	.106 (.035)*	.093 (.048)		
Step 7: Deviant peer association	.187 (.048)*	.032 (.060)	.068 (.038)*	.117 (.043)*	.029 (.048)	.071 (.050)	
Violence	.174 (.066)*	.000 (.066)	.071 (.031)*	.116 (.048)*	.083 (.047)	.017 (.057)	.171 (.075)*

Note. $N = 463$. Figure is path coefficient. Standard error is in parentheses.
$^*p < .05$.

significantly increase model fit, $\chi^2(28, n = 462) = 55.73$, $p = .001$, indicating that the strength of developmental paths differed for males and females. In follow-up analyses, we probed this interaction in each of seven models allowing the paths to differ at each step in the cascade. A significant interaction with gender was found for one of the seven models, predicting school failure, $\chi^2(4, N = 462) = 18.48, p = .001$.

This model predicting school failure freed across gender groups fit the data well, $\chi^2(24, N = 462) = 37.25$, $p = .041$, comparative fit index [CFI] = .976, Tucker-Lewis index [TLI] = .943, estimated root mean square error of approximation [RMSEA] = .049 (90% confidence interval = .010 – .078). For girls, school failure was significantly predicted by social context, $b = .164$, $SE = .067$, $Est./SE = 2.46$, $p < .05$, and by early parenting problems, $b = .196$, $SE = .082$, $Est./SE = 2.39$, $p < .05$, but not by lack of school readiness, $Est./SE = 1.24$, or by early externalizing problems, $Est./SE = -0.84$. The opposite held true for boys, with significant prediction from early externalizing problems, $b = .189$, $SE = .046$, $Est./SE = 4.15$, $p < .001$, and lack of school readiness, $b = .308$, $SE = .054$, $Est./SE = 5.73$, $p < .001$, but not by social context, $Est./SE = -0.91$, or early parenting problems, $Est./SE = 1.22$.

Tests of Interaction With Level of Initial Risk

The full model was contrasted with a model in which path coefficients were allowed to vary between the high-risk and normative groups. Loosening the constraint that the paths are identical significantly improved model fit, $\chi^2(28, n = 462) = 112.86, p < .001$, indicating that the strength of developmental paths differed for high-risk and normative groups. Of the seven domains predicting violence outcomes, one (deviant peer associations) yielded a significantly stronger path in the normative than in the high-risk group ($p < .05$).

Among the other 15 path coefficients tested and depicted in Table 5, 3 yielded a significant interaction involving level of initial risk. All 3 involved early harsh and inconsistent parenting. The relations between early harsh and inconsistent parenting and school social and cognitive readiness, parental monitoring, and deviant peer associations were stronger in the normative group than in the high-risk group.

Discussion

This study reports four major empirical findings that, together, support a dynamic cascade model of how serious violence develops across the life span from early childhood through adolescence. The major contribution is an understanding of how predictor domains operate in concert to predict violent outcomes. Findings indicate that (a) violent outcomes are multiply predicted from factors in diverse domains spanning early development, (b) these domains are intercorrelated and each domain predicts the next domain in development across childhood, (c) each succeeding domain partially mediates the effect of the immediately precedent domain, and (d) although domains intercorrelate and mediate each other, domains play unique and incremental roles in predicting later violent behavior.

Toward a Dynamic Cascade Model of the Development of Violent Behavior

Each of the seven predictor domains (early adverse context, harsh and inconsistent discipline, school social and cognitive readiness, early externalizing behavior problems, school social and cognitive failure, parental monitoring and communication, and deviant peer associations) was significantly related to adolescent violence. Consistent with the literature reviewed earlier, these findings also extend the literature to the relatively severe outcome of violent behavior and generalize these patterns across both male and female groups. The field's confidence in these domains as risk indicators is enhanced by these findings.

The current study provides the most detailed description to date of how these seven temporally distinct predictor domains are intercorrelated. All temporally adjacent domains were significantly related to each other, suggesting that they might provide partially redundant information in predicting violence outcomes. Indeed, each succeeding domain partially mediated the impact of the prior domain on violence outcomes. The redundancy is only partial, however. Each succeeding domain not only mediated the preceding domain, it also provided a significant increment beyond the previous domain in enhancing the prediction of violence outcomes.

This patterned sequencing is consistent with dynamic systems models (e.g., Granic & Patterson, 2006), and it provides a coherent developmental story of how violent behavior grows across childhood and adolescence in a dynamic cascade. The story involves reciprocal impact of parenting on peer relations and peer relations on subsequent parenting. It also involves reciprocal influences between the self and the environment. It explains how early risk is realized across time but also how each new developmental era affords new risk.

The theoretical model that has been supported here starts with children who are born into an adverse neighborhood or disadvantaged family context. This context places children at risk for adolescent violence partly because features of the context (perhaps stress, lack of resources, lack of support; McLoyd, 1990) make it difficult for parents to avoid harsh and inconsistent discipline with their young child. These harsh discipline styles not only account for part of the effect of adverse context on outcomes but they also enhance risk for violence outcomes.

In turn, a partial mechanism through which harsh and inconsistent discipline operates on later violence outcomes is by preventing the child from acquiring social and cognitive skills that are necessary for school social and academic success. These skill deficits include vocabulary deficits, poor social problem solving, hostile attributional biases, and emotion recognition deficits. They partly account for how early dysfunctional parenting leads to adolescent violence. These deficits are more proximal to the phenomenon of adolescent violence (both temporally and theoretically), and they enhance children's risk beyond that afforded by adverse contexts and early parenting. They also predict the child's display of externalizing conduct problems at the time of school entry, which becomes the path leading toward later adverse outcomes.

Externalizing conduct problems at school entry signals the "early starter" in Moffitt's (1993) model of life-course-persistent antisocial behavior and is an important part of the proposed cascade. Methodologically, it is important that this domain is included in the model because a primary alternative hypothesis to the proposed cascade is simply within-child consistency of behavior (from early conduct problems to later violence). Inclusion of this domain enabled testing of this alternative hypothesis, which was empirically rejected by tests that indicated that other domains provide significant increments in the prediction of adolescent violence beyond the prediction afforded by early conduct problems.

Next in the cascade is the role of school social and academic failure, which follows from early externalizing conduct problems. Not surprisingly, conduct problems lead to peer social rejection and academic failure, which account for some of the effect of conduct problems on long-term outcomes. Failure experiences with peers and academic subjects enhance risk for violence in adolescence and increase the likelihood of problem outcomes.

According to the theoretical model, one mechanism through which childhood school failure leads to adolescent violence is through its impact on the parent–child relationship and interaction during early adolescence. Just at a time when youths need monitoring, supervision, and communication with parents, the youths who are at greatest risk suffer from the least amount and poorest quality parenting in these tasks. Parenting during early adolescence not only mediates the impact of the child's previous school failure, it enhances the prediction of adolescent violence. Finally, one way that parental lack of monitoring and communication with a youth leads that youth toward violence is by allowing the youth to interact with deviant peers. Deviant peer associations are the most proximal factor in adolescent violence. They partially mediate the impact of poor parental monitoring, and they enhance this risk as well.

The reciprocal influences between the child and parent over time are especially noteworthy. The parent's early discipline strategies have an impact on the child's social and cognitive readiness for school, which affect conduct problem behavior. In turn, the child's experiences at school cycle back to exert an impact on parenting behavior in early adolescence, which then affects the youth's interactions with peers during adolescence. Bidirectional relations between domains of parenting and child–peer functioning across development have been hypothesized by transactional theorists such as Sameroff and Mackenzie (2003) but rarely have they been empirically demonstrated in longitudinal inquiry.

An important implication of the current findings is that it is premature to conclude that an early-starting antisocial 5-year-old is unequivocally destined for a life-persistent path toward violent outcomes. Although the risk is substantial, it is by no means certain. The findings reported here indicate that trajectories can be deflected at each subsequent era in development, through interactions with peers, school, and parents along the way. The theory of the early-starting antisocial child must account for the deflections in trajectories (e.g., positive outcomes in the face of early risk factors) that have been observed here.

Opportunities for Preventive Intervention

The reciprocal side of the finding that each new developmental era provides enhanced risk for violent outcomes is that each era also provides an opportunity for a change in the youth's developmental trajectory. Even though a child may be at risk due to being born into an adverse neighborhood context, that risk can be lessened by subsequent life events, most proximally the quality of parenting that the child receives during early childhood, especially during discipline encounters. In turn, even though the experience of harsh and inconsistent parenting places a child at risk for violent outcomes, that risk can be lessened by success at school in cognitive and social realms. Likewise, a difficult early school experience that places a child at risk for adolescent violence can be partially offset by parents who closely monitor and supervise their child and communicate with him or her. Finally, risk that is raised by parents who fail to monitor can be lessened if the youth's exposure to deviant peers is limited.

The implications for prevention are many. First, each era affords a new opportunity for targeted intervention in a specific domain that had not been encountered previously. The current findings provide specific targets for prevention at specific eras in development (e.g., during preschool, parenting interventions focused on discipline strategies should be targeted; during the early school years, child-focused intervention directed at enhancing cognitive and social skills and school success should be emphasized) . Second, because new risks arise with each new developmental era, preventive intervention cannot be deemed "over" until the child has passed through adolescence. Third, it appears that the most effective preventive interventions will address multiple aspects of a child's family and school life across multiple eras of development. It is not surprising that, indeed, the most effective preventive intervention programs comprehensively address multiple domains (e.g., CPPRG, 2004; Dishion & Kavanagh, 2000; Henggeler, Schoenwald, Bourduin, Rowland, & Cunningham, 1998; Tremblay, Pagani-Kurtz, Masse, Vitaro, & Pihl, 1995).

Contribution to Knowledge of Antisocial Development in Girls

Very few studies have included sufficient numbers of high-risk girls to make conclusions about developmental pathways toward violence in girls. The findings support the hypothesis that violent outcomes in girls follow largely similar developmental pathways as those for boys. Only one significant difference in pathways was detected, indicating that school failure was more a function of adverse context and parenting for girls than boys, whereas school failure was more a function of externalizing problems for boys than girls. Context, parenting, skills, and peer relations all operate to predict antisocial outcomes in girls in the same way that they do in boys.

Contribution to Methods in Longitudinal Inquiry

Sameroff and Mackenzie (2003) lamented the dearth of longitudinal studies and sophisticated methods that are available to test complicated hypotheses of transactional effects and reciprocal influences across time. Dodge, Coie, et al. (2006) cautioned that the diverse array of variables that have been correlated with antisocial outcomes beg for an integrated theory. The current study offers a novel approach to combining variables in a coherent manner that goes well beyond the simple (though powerful) approach of cumulating risk factors in a summative fashion. The approach requires clearly articulated hypotheses, data collected across multiple nonoverlapping time points, and a sufficient sample size. Variables have been combined into "domains" that represent coherent sets, but the method of combining variables differs critically from the traditional approach of latent variables analyses and SEM, which assume that variables are indicators that are "caused" by a latent construct. Instead, the current approach assumes that manifest variables can be aggregated into an "index" without assumptions of a single latent construct. The data-analytic methods are not new but are newly applied to social development. Dodge, Malone, et al. (2006) have applied similar methods with different domains of variables to understand how children grow into users of illicit substances.

Findings That Provide a Basis for Future Inquiry

Two findings provide the basis for further inquiry. First, findings of partial, rather than full, mediation indicate that precedent stages continue to predict later violence. It might be that risk induced by a prior stage imparts risk that endures in spite of subsequent events, or it might be that the current study simply failed to identify the processes that fully mediate later violence outcomes. Future studies should test hypotheses about other developmental pathways at each stage that might mediate violence outcomes. These other pathways might involve new variables within the same domains that were tested here (e.g., executive cognitive functions such as inhibitory control might be added to the cognitive readiness domain), or they could assess new domains altogether (e.g., quality of preschool experience, afterschool contexts). Furthermore, the categorization of mediation decisions into "full" or "partial" or "no" groups ignores quantitative differences in the magnitude of mediation. Future studies might employ alternate methods of quantifying mediation, using proportion of variance measures or new methods.

Second, it was found that the strength of factors in developmental pathways differed according to level of initial risk. Although not numerous or large, these findings suggest that future inquiry might focus on models of development that apply specifically to high-risk youth.

Finally, a third focus of future inquiry might be to address possible interaction effects among risk domains. That is, it is plausible, even likely, that the impact of one domain is altered (e.g., exacerbated, magnified, mitigated, muted) by variables in another domain. These hypotheses would be tested by interaction effects analyses that were not conducted here.

Limits of the Study

The limits of this study are substantial. They begin with the inescapable fact that these data, although longitudinal, are correlational and are subject to alternate interpretations of third-variable causation, selection factors, and spuriousness of relations. It is still plausible that child factors lead to each of the environmental factors measured here, although the unique increments afforded by different environmental variables suggests that multiple child factors would likely be involved. It is also plausible that each environmental factor is merely a proxy for an unmeasured other environmental factor that causes both the measured variable and its downstream correlates. Further, it may be the some effects that are ascribed to parenting or other environmental factors may be partially the result of genetic effects or gene X environment interaction. No data-analytic method can escape this possibility, but only randomized intervention experiments come closer to parsing cause from spuriousness.

A second limit is that these analyses do not rule out other plausible cascade models that include additional domains and variables. The findings reported here support a cascade model over a simple continuity-of-behavior model, but future studies will need to test competing cascade models against each other. A particular limit is that measurement began when children were 5 years old; thus, reciprocal relations among adverse context, parent characteristics, and very early behavior problems have not been tested. The current model is *a* cascade model, not necessarily *the only* cascade model.

The PLS modeling applied here has been subject to criticism that it makes assumptions about the aggregation of variables into index scores that operate as a unitary whole (Chin, 1995). This aggregation method departs from traditional latent variables approaches and is theoretically defensible in cases when the constituent variables clearly do not represent a unidimensional construct but have heuristic (and temporal) coherence nonetheless. A second concern about the PLS approach is that it may capitalize on chance through its optimization of weighting variables in predicting the downstream outcome. This criticism is the same at that cast toward canonical correlation. The PLS approach is indeed subject to that criticism in the tests of prediction of violent outcomes; however, the abundance of significant bivariate correlations between predictors and the violence outcome in the current study suggest that the conclusions made are not biased by the PLS approach. Furthermore, the tests of relations across PLS variates and the tests of mediation are not at all biased in this manner. They are as rigorous as tests in a structural equation model framework.

The complexity of the dynamic cascade theory suggests methods of data analysis that have not been followed in the current study, such as analyses of accelerating change and nonlinear relations among variables and person-centered approaches to testing hypotheses. The theory also suggests that numerous other variables and other points in time might have been selected for analysis instead of the ones that were chosen. The sequencing of domains for analysis required that any variable be located within a single time point, but realities of social development indicate that these same variables could be located at multiple time points. Furthermore, the arbitrariness of the unit of time as 1 year is obviously flawed. Dynamic development, transactional exchanges, and reciprocal influences undoubtedly occur within shorter time intervals than those measured here. Although the findings support the transactional nature of the relationship between child and parent, undoubtedly these transactions are far more frequent and powerful than could be captured by the current design, which limited measurement time lags to a 1-year unit. Future studies might well employ time units that are theoretically selected to represent the unit of hypothesized change in a developmental sequence, even allowing for unequal time units if theory dictates.

Conclusions

Even with these numerous caveats, the current study offers a novel dynamic cascade model of the development of serious violent behavior in adolescence, innovative use of methods of aggregating and analyzing developmental data, and empirical findings that inform developmental theory as well as preventive intervention. These methods await application to other developmental phenomena.

Investigating Preschoolers' Categorical Thinking About Gender Through Imitation, Attention, and the Use of Self-Categories

Diana M. Grace and Barbara J. David

Michelle K. Ryan
The University of Exeter

Whereas traditional theories of gender development have focused on individualistic paths, recent analyses have argued for a more social categorical approach to children's understanding of gender. Using a modeling paradigm based on K. Bussey and A. Bandura (1984), 3 experiments ($N = 62$, $N = 32$, and $N = 64$) examined preschoolers' (M age = 52.9 months) imitation of, and memory for, behaviors of same-sex and opposite-sex children and adults. In all experiments, children's imitation of models varied according to the emphasis given to the particular category of models, despite equal attention being paid to both categories. It is suggested that the categorical nature of gender, or age, informs children's choice of imitative behaviors.

Few things characterize children's lives as much as gender. From birth, children's environments and experiences differ based purely on their sex (Condry & Condry, 1976; Rheingold & Cook, 1975; Rubin, Provenzano, & Luria, 1974). Boys and girls receive differential treatment both at home (Siegal, 1987) and at school (Tittle, 1986), and this occurs against a backdrop of media portrayals further differentiating between the roles and status of men and women (Durkin, 1985).

Children themselves also play an active role in perpetuating this ubiquitous role of gender. At around 30–36 months of age, children display a marked preference for same-sex peers (LaFreniere, Strayer, & Gauthier, 1984; Maccoby & Jacklin, 1987; Powlishta, Serbin, & Moller, 1993), with these preferences increasing throughout childhood. By preschool age, 50% of children's play involves only opposite-sex peers (Fabes, Martin, & Hanish, 2003; Maccoby & Jacklin, 1987). Such same-sex preferences occur independent of parental, or other adult, interactions; they increase when adults are not present (Maccoby & Jacklin, 1987; Thorne, 1986); and they appear resistant to attempts to change (Serbin, Tonick, & Sternglanz, 1977). Although girls tend to initiate same-sex play more than boys at age 3 (Serbin, Moller, Gulko, Powlishta, & Colburne, 1994), this gender difference is reversed, and even heightened, by age 5 (Pitcher & Schultz, 1983).

The phenomenon of same-sex preference also becomes one of cross-sex avoidance, as it becomes equally important not to play with members of the opposite sex as it is to play with members of the same sex (e.g., Feiring & Lewis, 1987). This is particularly the case for boys who, even in the toddler years, actively avoid "not male" activities (Fagot, 1985a). This proclivity for gender differentiation often leads to a view of gender differences as inexorable and inevitable (a view that is explicitly challenged by the current research) and has played a role in theoretical explanations looking to within-sex rather than between-sex differences.

Despite the recognition that sex differences, and the display of sex-typed preferences, tend to occur in group settings, theories devoted to understanding gender development traditionally focused on gender development as a uniquely individual process (e.g., Bem, 1981, 1984; Freud, 1924, 1933; Kohlberg, 1966; Martin & Halverson, 1981, 1983). Being male or female, however, is not only about the individual; it implies membership of one category or another. Such explicit recognition of the group, or categorical, nature of gender has influenced more recent theoretical explanations and helps to explain why the adoption of gender norms and behaviors is essentially unrelated to individual attributes, or degree of sex typing, of the children who comprise these groups (Maccoby & Jacklin, 1987; Powlishta, 1989, cited in Maccoby, 1990). Moreover, the different experiences that boys and girls have in their same-sex groups may actually reinforce the importance of gender as an organizing property of these peer groups (Fabes et al., 2003; Maccoby, 1990) and may supersede innate differences or preference for playstyles that may have prompted the sex segregation (Fabes et al., 2003; Martin & Fabes, 2001).

In addition to organizing information, gender can be used to inform children about appropriate behaviors—an idea that may help explain why young children imitate others of the same sex as themselves. This seems to be particularly the case for boys who appear just as intent on not imitating girls as they are on imitating boys and are more likely than girls to reject, or tease, each other for engaging in opposite-sex behavior (Feiring & Lewis, 1987). Again, however, such a view assumes that gender effects operate in a fixed way. The current research was designed to explore this idea by examining the notion of similarity to peers (and/or same-sex adults) and the contexts in which (gender-relevant) information is provided. The social categorical, or group-based, nature of gender is emphasized throughout.

Central to this idea of gender as a group phenomenon is work by Bussey and colleagues (Bussey & Bandura, 1984; Bussey & Perry, 1982) whose modeling studies demonstrate that adoption of same-sex behaviors, and rejection of opposite-sex ones, depended on those behaviors being seen as normative, or not, for a number of men or women: It appeared that children waited to see if a particular behavior was exhibited by all the men or all the women before adopting (or rejecting) it for themselves. This, the authors argue, reflects how children see their social environment. On any given day, children are exposed to numerous people exhibiting a variety of behaviors. What they encode as gender normative, however, are those behaviors exhibited most frequently and consistently by multiple members of each gender category.

This is similar to a more extreme idea put forward by Harris (1995, 1998) who claims that children are influenced more by other children than by parents or other adults. She emphasizes the group basis of lasting influence by making a clear distinction between dyadic friendships and group memberships (Harris, 1998). The effects of dyadic relationships are claimed to be short-lived, with any long-term influence attributed to the fact that friends tend to be members of the same social groups. Thus, Harris (1998) claims it is the processes functioning within the child's peer group that are responsible for the lasting transmission of culture and the resultant adult outcomes.

This approach, however, relies on a similarity-based account of identification. That is, because children see themselves as similar to other children, or because girls (or boys) see themselves as similar to other girls (or boys), they identify with, and are influenced by, these similar others or those who share category membership. Such an analysis, however, views both similarity and difference as fixed features of a stimulus.

Gender as a Group Process—The Role of Categorization

The role of categorization has been increasingly implicated in empirical investigations concerning young children's social category knowledge, although these have typically focused on primary school–aged children (e.g., Bigler, Jones, & Lobliner, 1997). These investigations have included such domains as gender (e.g., Powlishta, 1995b), race and ethnicity (e.g., Nesdale & Flesser, 2001; Verkuyten, 2002; Yee & Brown, 1992), national identity (e.g., Barrett, 2000), and, to some degree, essentialist beliefs about categories (e.g., Heyman & Gelman, 2000). Much of this work has been explicitly informed by social identity theory (SIT; Tajfel & Turner, 1986) and, to a lesser extent, self-categorization theory (SCT; Turner, Hogg, Oakes, Reicher, & Wetherell, 1987).

According to this approach, social categorization is both adaptive—in that it provides information about the social world—and a reflection of our active engagement with that social world (e.g., Oakes, Turner, & Haslam, 1991). This view thus provides a crucial link between external differences (e.g., gender differences) and how these can be reflected, and represented, within the person.

An important outcome of the categorization process that has received much attention is the perceptual distortion (such as the accentuation of similarity and difference) that pertains to (same-sex) similarity or (same-sex) preference. Although accentuation effects have been demonstrated using racial categories (Hewstone, Hantzi, & Johnston, 1991; Taylor, Fiske, Etcoff, & Ruderman, 1978), gender categories (Frable & Bem, 1985; Jackson & Hymes, 1985), and even sexual preference (Walker & Antaki, 1986), these effects need not necessarily be considered an automatic outcome of the categorization process but can vary according to the appropriateness and meaningfulness of the salient categorization (McGarty & Penny, 1988; McGarty & Turner, 1992).

These principles of accentuation (of similarities and differences) have also been applied to categorizations of the self (Turner, 1984), whereby self-categorization in terms of a social identity maximizes both differences between one's in-group and an out-group and similarities between oneself and other in-group members. Similarly, self-categorization in terms of one's personal identity maximizes perceived differences between oneself and other individuals while simultaneously minimizing intraindividual (within oneself) inconsistencies.

Such an approach explicitly rejects the notion of similarity (or difference) as a fixed feature of a stimulus (cf. Medin, Goldstone, & Gentner, 1993; Murphy &

Medin, 1985; Yzerbyt, Rocher, & Schadron, 1997). Similarities (within categories) and differences (between categories) are guided not only by a comparative frame of reference but also by the perceiver's own expectations and theories (Brown & Turner, 2002). Children categorize children and adults (and boys and girls) not only because of perceptual similarities and differences but because there is some psychological reason to do so. They expect children and adults (and boys and girls) to look and behave differently partly because they have seen them do so and partly because they have seen the consequences of these different behaviors.

Children's Understanding of Social Categories

Applying a self-categorization approach to children's understanding of themselves and others suggests that children define themselves in a number of ways. They may regard themselves as children, as boys (or girls), as members of their family (the Johnsons or the Billington-Smythes), or even as "tadpoles" (in their learn to swim class). This self-definition is determined by both the current situation and the children's own expectations about these categorizations.

Such an approach has indeed been recently articulated by Bigler and Liben (2006, 2007) whose developmental intergroup theory (DIT) outlines the mechanisms by which children develop social stereotypes and prejudiced beliefs. This work is consistent with the adult social psychological literature in focusing on the social psychological processes implicated in such thoughts and behaviors and in emphasizing the generality of these processes. That is, these psychological processes are not confined to the domain of racial, or ethnic, prejudice but apply to the range of intergroup, or intercategory, domains, including gender.

The Current Research

The overall aim of the current research, therefore, was an empirical investigation of social categorization (specifically, the notions of variable self-definition, similarity as a reflection of perceptual and contextual features, and the effect of salience manipulations) in the domain of gender development. The three studies presented focused explicitly on examining the acquisition of gender understanding as a social category. We sought to investigate how this particular social category functions, whether it differs from other social categories (in particular, age), and what the implications are of belonging to one of those social categories (e.g., male as opposed to female). Given that children are capable of using one of a number of social categories, we suggest that the importance of gender to children may be a consequence of the importance it is afforded, that is, its relative salience within a given context.

Relevant processes in this investigation included the imitation of observed others and the attention paid to information presented. Given its importance in the socialization process, modeling, or imitation, was a major focus of this work using a modeling paradigm (after Bussey & Bandura, 1984), which we describe subsequently.

Experiment 1

The first experiment aimed to extend Bussey and Bandura's (1984) findings of sex-linked modeling behaviors. In this earlier work, children watched videos in which a different set of behaviors was performed by adult male and female models before being given an opportunity to enact these behaviors. Although no social context had been provided for the behaviors, children showed a strong preference for imitating the same-sex models, despite demonstrating equal recall of the behaviors performed by both the male and the female models. Given the increased emphasis since the original study on nongendered play and education in early childhood settings (e.g., Yellond, 1998) and the expression of this by early childhood teachers (e.g., Cahill & Adams, 1997), the first aim was to investigate whether these preferences still exist.

The second, and related, aim was to investigate children's sex-linked modeling with peers, or other children, not only to determine the robustness of sex-linked modeling but also to pose a direct test of Harris's (1995, 1998) assertions that children are more influential models than adults. Although recognizing that this was in no way an attempt to measure lasting influence, the comparison allowed us to examine variable self-categorization in children as a result of changes in contextual features.

A measure of attention paid to models provided important information for children's imitative behaviors. If, for example, children imitate same-sex models more than opposite-sex ones, this does not tell us whether children simply ignored the information provided by the opposite sex in the first instance or if they paid attention to all the information provided. The former suggests a relatively straightforward process involving identifying self and others (models) as male or female and then finding it appropriate to imitate the behavior of the person similar to themselves (the same-category exemplar). If, however, the latter is the case, it implies a more complex process involving consciously choosing an appropriate behavior from a wider stimulus array. It also implies that some behaviors are consciously rejected as being inappropriate behaviors to enact.

In line with Bussey and Bandura (1984), it was predicted that both boys and girls would imitate same-sex models more than opposite-sex models. Although Bussey and Bandura found greater same-sex modeling by boys, this would not be expected if boys and girls use gender categories in the same way.

With respect to modeling of adults and children, an extrapolation of Harris' (1998) argument would predict more modeling of child models than of adult models, although more contemporary social developmental understandings (e.g., DIT, extrapolations of SCT) would predict no difference between these (at least in situations of low gender salience and/or low comparative context). Because these predictions have not previously been investigated, this was of particular interest in the current study.

Finally, age of participants was analyzed to investigate any developmental change that might occur, even within the limited age span. It was anticipated that older children would have had more exposure to gender socialization pressures and this would manifest itself in greater demonstration of same-sex modeling than by younger children.

Method

Participants. Participants were 32 girls and 30 boys from university child-care centers in Canberra, Australia. They ranged in age from 39 to 68 months ($M = 53.98$ months, $SD = 6.48$). No specific data on children's socioeconomic status or race/ethnicity were obtained, although the majority of children attending these centers have parents either working or studying at the university and represent a somewhat diverse range of ethnic backgrounds. Participants had written parental consent and provided verbal consent themselves at the start of each session. All participants were able to understand and speak English.

Design. The study involved a 2 (sex of participant: boy, girl) × 2 (age of models: adult, child) × 2 (sex of models: male, female) mixed factorial design. The last factor was the within-participants factor, as all children saw videos of both male and female models.

Procedure. Participants watched one of four videos depicting three male and three female models (either all adults or all children), where all the males performed one set of behaviors and all the females another. The behaviors performed by the male and female actors were counterbalanced in alternative versions of the videos. As with the child participants, the models themselves came from a range of ethnic backgrounds, although this was not emphasized in any way, nor was it commented on by any child.

After being introduced to the experimenter in a classroom situation, each participant was individually brought into the experimental room (a separate room at each child-care center). The room was set up in a manner identical to what they would see in the video, with chairs, a table with two Mickey Mouse hats, another table with a box and a toy koala, a pinboard on one wall, and a television. The child sat next to the experimenter to watch the video.

The sequences of behaviors performed by the models were those described in Bussey and Bandura (1984). In one sequence, all the male actors chose a black Mickey Mouse hat, which they placed on their head with the Mickey Mouse symbol to the front and performed a corresponding behavior sequence. In the alternative sequence, actors chose a red Mickey Mouse hat that they wore with the Mickey Mouse symbol to the back and performed the alternative behavior sequence. Each sequence of behaviors comprised 14 separate behavioral components.

After watching the entire video, each child was asked by the experimenter if he or she would like to play the game he or she had just seen. The experimenter reminded each child first to choose a hat, the only prompt provided at this stage of the study. Each child was then allowed to play with the toys as shown in the video. This behavior served as the primary "imitation" dependent measure. Where parental consent had been provided, the child's performance was videotaped.

Memory task/manipulation check. Following the imitation task, each child was asked to recall the behaviors of the male and female models. For each of the 14 behaviors, the experimenter provided participants with specific prompts, such as "Which hat did the men (boys)/women (girls) choose?" The order of questions (male followed by female or female followed by male) was counterbalanced across participants. Responses were recorded on a checklist by the experimenter.

At the end of each session, the children were thanked for their participation and allowed to choose a sticker to take home.

Results

Modeled (imitation) behavior. A checklist of the behaviors was used to record each child's performance. The total number of behaviors was calculated for each of the four categories: (a) same-sex behavior, (b) opposite-sex behavior, (c) other (i.e., new or random) behavior, and (d) nothing (i.e., no behavior performed). The final category was not used in the analyses because it was of no theoretical interest and provided no additional information to what was provided by the other categories.

Videos of 39 participants were analyzed by an independent rater using the same four categories. Using Cronbach's alpha, reliability coefficients for each of the 14 behaviors ranged from .71 to 1.00. In an attempt to reach perfect agreement, both raters reanalyzed the videos. Disagreements occurred only when tape quality was poor. The subsequent studies were not videotaped due to issues concerning parental consent and the sheer impracticality of the procedure. Given the high accuracy of the primary rater, however, this was not considered a problem.

The data were analyzed in a 2 (sex of participant: boy, girl) × 2 (age of model: adult, child) × 3 (modeled behaviors: same sex, opposite sex, new behavior) analysis of variance (ANOVA), with the last factor being within participants. Means and standard deviations appear in Table 1. A significant main effect for modeled behaviors, $F(2, 116) = 20.38, p < .001$, partial $\eta^2 = .26$, indicated greater performance of same-sex modeling ($M = 3.31$) than either opposite-sex modeling ($M = 1.58$) or performance of a new behavior ($M = 1.28$). This was qualified by a significant Modeled Behaviors × Age of Model interaction, $F(2, 116) = 3.04, p = .05$, partial $\eta^2 = .05$. Children imitated same-sex behaviors more when they were modeled by adults ($M = 3.89$) than when they were modeled by children ($M = 2.73$), $t(60) = 1.95, p = .05$; children responded (nearly) equally to opposite-sex adult ($M = 1.58$) and child ($M = 1.59$) models and performed new behaviors more when models were children ($M = 1.52$) than when they were adults ($M = 1.04$), although this difference did not reach significance, $t(60) = -1.83, p = .07$. The Modeled Behaviors × Sex of Participant interaction was nonsignificant, $F(2, 116) = 2.30, p = .11$, partial $\eta^2 = .04$.

Table 1

Experiment 1: Mean Number (Standard Deviations) of Modeled Behaviors of Adult and Child Models

	Adult models		Child models	
	Girls	Boys	Girls	Boys
Same sex	4.38 (2.90)	3.40 (2.29)	3.19 (2.01)	2.27 (2.02)
Opposite sex	1.63 (1.54)	1.53 (1.81)	1.38 (1.54)	1.80 (1.66)
New behavior	0.75 (0.93)	1.53 (0.98)	1.38 (1.26)	1.67 (0.90)

Although the overall three-way interaction was statistically nonsignificant, our precise hypotheses led us to explore separately imitation of adult and child models.

Imitation of adult models. Both girls and boys imitated same-sex adult models significantly more than opposite-sex adult models, $F(2, 58) = 16.75, p < .001$, partial $\eta^2 = .37$. However, the linear decrease in behaviors from same-sex imitation through opposite-sex imitation to new behaviors was evident only for girls. Whereas girls' performance of opposite-sex behaviors was significantly greater than their performance of new behaviors, $t(15) = 2.05, p = .05$, boys were no more likely to perform opposite-sex behaviors than new behaviors, $t(14) = 0.34, p = .74$. In other words, boys were no more likely to imitate a woman than to invent entirely new behaviors.

Imitation of child models. The pattern of imitating child models also differed for girls and boys, $F(2, 58) = 4.69, p = .013$, partial $\eta^2 = .14$. Although girls' same-sex modeling was significantly greater than their opposite-sex modeling, $t(15) = 2.72, p = .01$, their performance of opposite-sex modeling was identical to two decimal places to that of new behaviors. Strikingly, however, the amount of behaviors in each of the three categories did not significantly differ for boys, $F(2, 28) = 0.52, p = .60$. Boys were no more likely to imitate same-sex child models than they were to imitate opposite-sex child models or to perform a completely new behavior.

Age of participants. To investigate the possibility of a developmental increase in imitation of models, even at this young age, the above analyses were again performed to include age of participants. A median split was used to divide older from younger participants: the median age was 55 months. Again, the strong main effect for modeled behaviors emerged, $F(2, 108) = 15.39, p < .001$, partial $\eta^2 = .22$. Age of participant did not enter into any significant main or interaction effects.

In summary, there was clear evidence of children's same-sex imitation that, contrary to Bussey and Bandura (1984), did not statistically differ for girls and boys. Importantly for the present study and for Harris's (1995, 1998) contention concerning the prime importance of peers, children imitated behaviors performed by adult models more than when those same behaviors were performed by child models.

Memory task/manipulation check. For this task, children were specifically asked what actions the male or female models had performed. The data were summed to produce the following: (a) correct recall of same-sex models' behavior, (b) correct recall of opposite-sex models' behavior, (c) incorrect recall of same-sex models' behavior, and (d) incorrect recall of opposite-sex models' behavior. The data were analyzed in a 2 (sex of participant: boy, girl) × 2 (age of model: adult, child) × 4 (memory for models) mixed-model ANOVA, with memory for modeled behavior as a within-participants factor. Means and standard deviations appear in Table 2.

Strong main effects for memory for modeled behavior, $F(3, 174) = 21.28, p < .001$, partial $\eta^2 = .27$, and for age of model, $F(1, 58) = 15.58, p < .001$, partial $\eta^2 = .21$, were qualified by a significant Memory for Modeled Behavior × Age of Model interaction, $F(3, 174) = 35.11, p < .001$, partial $\eta^2 = .12$. Of particular interest, children's correct recall of same-sex adult models' behavior ($M = 6.13$) was superior to their correct recall of those same behaviors when performed by child models ($M = 3.65$), $t(60) = 4.28, p < .001$. Similarly, their correct recall of opposite-sex models' behaviors was superior for adult models ($M = 5.75$) than for child models ($M = 3.55$), $t(60) = 3.80, p < .001$. Children's incorrect memory did not differ for adult and child models. Rather than being affected by the sex of model, children's recall of behaviors, or more specifically their correct recall of behaviors, was affected by the age of the models enacting those behaviors, with more correct recall of adult behaviors. No other main or interaction effects were found. As with the imitation measures, the analyses were repeated including age of participants. No effects were found.

Discussion

Consistent with Bussey and Bandura (1984), children showed a strong preference for imitating same-sex models. The present study extended the previous work by showing that this preference for same-sex imitation was maintained when models were children as well as when they were adults. It must be noted, however, that the frequency of behaviors not performed was quite high (over half of all possible behaviors); we address this overall rate of imitation in our next studies.

Table 2
Experiment 1: Mean Number (Standard Deviations) of Recalled Behaviors of Adult and Child Models

	Adult models	Child models
Same sex correct	6.13 (2.55)	3.65 (1.98)
Opposite sex correct	5.75 (2.59)	3.55 (1.89)
Same sex incorrect	2.35 (1.11)	2.74 (1.14)
Opposite sex incorrect	2.67 (1.58)	2.78 (1.03)

Bussey and Bandura's (1984) finding of greater same-sex modeling by boys than by girls was not replicated in the current study. Furthermore, and contrary to predictions derived from Harris (1995, 1998), children imitated same-sex models more when those models were adults than when they were children.

Clearly, however, children responded to the gender categories provided. Specifically, we argue that children chose to enact the behaviors performed by the category of people they saw as most appropriate to imitate. With respect to gender, it could also be said that the children saw same-sex people as most similar to themselves. However, with respect to age categories it could not be argued that the children saw themselves as more similar to the other children and hence decided to imitate them to a greater extent. Indeed, the current findings indicate the reverse: Children imitated the adult models to a greater extent than the child models, suggesting that (perceptual) similarity to other children was not sufficient to produce imitation of perceptually similar (i.e., same-age) models. This is inconsistent with predictions by Harris (1995, 1998).

It is possible, however, that the children recognized the authority of adults and hence saw it appropriate to imitate adults' actions. Children also have considerable experience imitating adults, especially with respect to gender-related activities. However, given the amount, and intensity, of reinforcement provided by peers for gender stereotypical behavior—even at the age of 3 or 4 years (e.g., Huston, 1983), along with the amount of time children spend in unstructured freeplay sessions, it is unlikely that they would have more experience imitating adults than children.

What makes the current findings particularly remarkable is that the behaviors performed could best be described as behaviors more typically performed by children. In no way could the modeled behaviors (i.e., selecting toy hats, playing with toys) be described as "adult behavior." If, indeed, children are exposed to adults behaving like this, as in the preschool setting, they are equally exposed to children behaving the same way. The absence of a main effect for age of model indicates that children did not simply imitate adults more than children; rather, they imitated same-sex adults more.

In addition to examining children's actual behavior, an important component of the present study was the attention paid to models. That no sex differences were found indicates children did pay equal attention to male and female models or, at the very least, made no differentiation between them. Their correct recall of both males and females did not differ whether the models were adults or children. Thus, if children paid equal attention to both sexes, as evidenced by their recall scores, yet chose to enact mainly behaviors performed by members of their own sex, it suggests that children were not differentially processing gender-related information.

Because the only way children could be classified with adults in this instance is in terms of gender, the very fact that they paid greater attention to, and later imitated, adults suggests that same-sex adults are perceived as highly appropriate conveyors of in-group norms with respect to gender categories. However, because no condition in the present study required children to choose between adults and children directly, interpretations in this vein must be limited. This is addressed in Experiments 2 and 3.

Experiment 2

Although the results of Experiment 1 found no evidence for the superiority of peer, in preference to adult, influence, a criticism of that study was the inclusion of age of model only as a between-participants variable: Participants were not given the choice to model adults or children. The primary aim of Experiment 2, therefore, was to directly compare children's modeling of, and attention paid to, adults and other children. This was achieved by removing gender from the design: Child participants were shown videos of adult and child models, only of their own sex.

Another shortcoming of Experiment 1 was that the overall amount of modeling was relatively low, compared to the number of actions the participants were shown, and hence given the opportunity to imitate. Presumably, this was due to the difficulty of the task: Child participants viewed the entire behavior sequences and were then asked to perform the actions they saw without any prompts from the experimenter. Although this appeared to be the procedure used by Bussey and Bandura (1984), subsequent communication with the first author revealed that they had, in fact, shown the video in segments before the associated opportunity for imitative behavior. Hence, both the design of the study and the modeling task were simplified for Experiment 2.

Method

Participants. Participants were 17 boys and 17 girls attending a university-based child-care center in Canberra, Australia. Their ages ranged from 41 to 64 months (M = 54.21 months, SD = 7.07). As with Experiment 1, participants' parents were predominantly university staff and/or students from a range of ethnic backgrounds. Participants' parents provided written consent, and children provided verbal consent to child-care staff and to the experimenter.

Design. The study involved a 2 (sex of participant: boy, girl) × 2 (age of models: adult, child) mixed factorial design. Age of models was a within-participants factor, as children saw videos of adult and child models who were the same sex as themselves. The models in the videos were those from the previous experiment.

Procedure. As with Experiment 1, participants were tested individually. Two new behavior scripts were introduced in this study and two (counterbalanced) versions of each video were used. The behavior sequences in this study were comparable to those in Experiment 1: Models selected either a green or a white Mickey Mouse cap and, accordingly, enacted one of the two behavior sequences. As with Experiment 1, each behavioral sequence comprised 14 behavioral components.

After watching the video, children were again given the opportunity to model the behaviors they had seen. An edited version of the video was used, showing three or four actions of one adult and one child model at a time. The sequence of 14 behaviors was thus divided into five segments, with a break in the video to allow the participant to perform the preceding actions before showing the next behaviors. Behaviors were recorded on a checklist by the experimenter.

Following this, the same memory task used in Experiment 1 was administered. At the end of each session, children were thanked for their participation, allowed to choose a sticker to take home, and returned to the group play area.

Results

Modeled behavior. Although the video sequence contained 14 separate behaviors performed by each of the models, this number was reduced to 12 for coding purposes. One of the behaviors (a verbal statement) was omitted because the experimenter always clarified the left or right side with the participant when he or she was placing the sticker onto the pinboard. In addition, no participant said either of the final utterances, so this behavior was also omitted.

Hence, the remaining 12 behaviors were coded into one of the four categories (adult behavior, child behavior, new behavior, and no behavior performed).

The total number of behaviors in each of the four categories was summed. Due to the change in procedure from Experiment 1, the number of no behavior responses was much lower (20% of all modeling responses). Because of this, and consistent with Experiment 1, this category was omitted from analyses. Thus, a 2 (sex of participant) × 3 (modeled behavior: child, adult, new) mixed-model ANOVA, with modeled behavior as a within-participants factor, was performed.

This revealed a significant main effect for modeled behavior, $F(2, 64) = 33.09$, $p < .001$, partial $\eta^2 = .51$, indicating that children (both boys and girls) modeled other children ($M = 5.50$, $SD = 2.21$) significantly more than they modeled adults ($M = 3.38$, $SD = 2.35$), $t(33) = 3.02$, $p = .01$. Similarly, children's modeling of adults was significantly greater than their performance of new behaviors ($M = 0.71$, $SD = 1.45$), $t(33) = 4.86$, $p < .001$. Presumably due to the change in procedure for the modeling task, children's performance of a new behavior was extremely low in this study. Importantly, no sex differences were found; the patterns of modeling by boys and girls did not differ significantly from each other.

Consistent with Experiment 1, analyses were performed involving age of participants. Using a median split on children's age (median age = 54 months), a 2 (sex of participant) × 2 (age of participant) × 3 (modeled behaviors) mixed-model ANOVA was conducted. Again, there was a strong effect for modeled behaviors, $F(2, 60) = 32.11$, $p < .001$, partial $\eta^2 = .52$, along with a main effect for age of participant, $F(1, 30) = 4.86$, $p = .03$, partial $\eta^2 = .14$: Older children ($M = 3.39$, $SD = 0.48$) performed more behaviors than younger children ($M = 3.01$, $SD = 0.48$). No other main or interaction effects were found.

Memory for models. Questions concerning child behaviors and adult behaviors were each classified into three categories: correct, incorrect by substituting the opposite behavior, and other. The data were then analyzed in a 2 (sex of participant) × 4 (memory for models: child models correct, adult models correct, child models incorrect by adult behavior, and adult models incorrect by child behavior) mixed-model ANOVA, with memory for models as a within-participants factor.

The significant main effect for memory for models, $F(3, 96) = 12.65$, $p < .001$, partial $\eta^2 = .28$, merely revealed that participants' correct recall of behaviors (child models: $M = 5.18$, $SD = 2.05$; adult models: $M = 5.09$, $SD = 2.35$) was greater than their incorrect recall (child models: $M = 3.03$, $SD = 1.28$; adult models: $M = 2.89$, $SD = 1.34$). Age of participants was also investigated in a 2 (sex of participant) × 2 (age of participant) × 4 (memory) mixed-model ANOVA. No effect for age of participant was found. Only the main effect for memory was replicated, $F(3, 90) = 12.32$, $p < .001$, partial $\eta^2 = .29$.

Discussion

In this study, both boys and girls demonstrated a clear preference for imitating same-sex child models over same-sex adult models, and this occurred more than their tendency to perform an unseen behavior. No sex differences were found. Perhaps not surprisingly, older children performed more behaviors than did younger children. Older children are both more able to and more practiced at performing actions exhibited by other people.

Despite the strong preference for age-related imitation shown in the modeling task, memory for adult and child models did not differ. Moreover, children's correct recall was much greater than their tendency to misattribute behaviors to either the adult or the child models, which, in turn, was greater than their tendency to provide new responses. As was the case with gender categories in Experiment 1, children paid equal attention to models in both categories, yet chose to behave in accordance with the category most relevant to themselves. In this study, that category was age, and children modeled the behaviors of other children.

In contrast to Experiment 1, the results of the present study lend support to Harris's (1995) assertions. In a more explicit test of her claims, and removing gender as a possible confound, child participants imitated children more than they imitated adults. However, the removal of gender from the design of the present study actually changed the context from that of the first study. In the first study, the only available categorization was sex. Children overwhelmingly chose to imitate people (both adults and children) of their own sex. Although their imitation of same-sex adults was greater than that of children, their imitation based on gender was greater than that based on age. In the present study, where children only saw models who were the same sex as themselves (thereby eliminating any reason for categorization along gender lines), they imitated the child models (same-age imitation) to a greater extent than they imitated adult models. Such contextual changes, as occurred in these two studies, made it appropriate for children to act (i.e., to imitate) in accordance with their membership of the particular salient category:

Boys imitated males and girls imitated females in the first study, whereas children of both sexes imitated children, in preference to adults, in the second study.

These results provide additional evidence of young children's capacity to self-categorize according to either age or gender. This is similar to Sani and Bennett's (2001) study in which 6- and 7-year-olds varied their choice of stereotypical descriptive traits for groups depending on the comparative context in which their choice was made. Such contextual changes are reflected in the self-categorical choices made by the children—as demonstrated by children's descriptive terms (Sani & Bennett, 2001) or by behavioral measures such as imitation (in the current studies). Thus, if children are able to identify with, and therefore imitate, either same-sex people (regardless of age) or same-age people (regardless of sex) depending on which category (age or sex) was salient at the time, this could be demonstrated by experimentally manipulating (age and sex) category salience. This was explored in Experiment 3.

Experiment 3

There is abundant evidence demonstrating the effects of contextual changes on intergroup processes with adults (e.g., Haslam, Oakes, Turner, & McGarty, 1995; Platow, Mills, & Morrison, 2000). Considerably less research has been conducted with children, with most focusing on primary school–aged children. Notably, Bigler and colleagues (Bigler, 1995; Bigler, Brown, & Markell, 2001; Bigler et al., 1997; Patterson & Bigler, 2006) have shown that children as young as preschool age show in-group biases on the basis of novel, randomly assigned groups when these groups are made salient by authority figures via the labeling and use of the groups (though not when those groups are ignored) and increase their use of gender stereotyping as a result of teachers' labeling and use of gender in the classroom (Bigler, 1995). Similarly, Powlishta (1995a, 1995b, 2000) has demonstrated the importance of the intergroup context in children's judgments concerning gender. With the exception of Patterson and Bigler (2006), the youngest children in these studies were kindergarteners. Moreover, variations in context were only due to variations in the emphasis placed on gender in the different settings (similar to Experiments 1 and 2).

Our third experiment was therefore designed to vary the context (by manipulating both age and gender salience) in which children would be presented with the exact same information (similar to Ryan & David's, 2003, work with adults). Specifically, if age were made salient, it was hypothesized that children would imitate other children (in preference to adults and regardless of sex), but when gender was made salient, girls would imitate females (in preference to males and regardless of age) and boys would imitate males (in preference to females and regardless of age). All the while, however, children would be expected to pay equal attention to, and therefore be able to recall, both sets of information equally. This is because the behavioral choice concerning which behavior to adopt is, it is suggested by the previous two experiments, indeed a choice.

Method

Participants. Participants were 32 girls and 32 boys from four child-care centers in Canberra and Melbourne, Australia. Their ages ranged from 40 to 66 months (M = 50.5 months, SD = 7.64), and the children came from a variety of ethnic backgrounds. All participants had written parental consent and provided verbal consent themselves.

Design. The study involved a 2 (sex of participant) × 2 (category salience: age, gender) between-participants factorial design. Participants watched one of four videos depicting same-sex adult and opposite-sex child models (two videos were counterbalanced versions). The models and behavior sequences were those used in the previous experiments.

Procedure. Children were again tested individually in a separate area of the child-care center. Before watching the video, they were asked about activities that children and grown-ups (age salience condition) or males and females (gender salience condition) like to do. Specifically, they were asked, "What are some of the things that children (or ladies and girls) like to do?" followed by "What are some of the things that grown-ups (or boys and men) like to do?" They were then given a sorting task. Children were shown a series of 20 laminated color pictures, presented one at a time, which they were asked to sort into two piles: either children and adults (age salience condition) or males and females (gender salience condition).

Children were then asked to watch a video (involving same-sex adults and opposite-sex children) and given the opportunity for imitative behavior. The simplified modeling task from Experiment 2 was used, with the experimenter asking the child about his/her actions if the actions were unclear.

In an attempt to increase recall responses, a modified version of the memory task was administered. Rather than allowing for free recall, as had been the case in the previous studies, children were given a forced-choice format. This consisted of both behavioral options that had appeared in the video. In editing the videos, the final utterance when the models returned to their chair was deleted. Hence, participants were asked a total of 16 memory questions, 8 pertaining to each of the models. Again, the order of presentation of these questions was counterbalanced across participants.

Results

All children correctly sorted all 20 pictures into the correct piles according to the (age or gender) directions they had been given.

Modeled behavior. The eight behaviors were coded into one of the four categories used in Experiments 1 and 2, and a 2 (sex of participant) × 2 (category salience: age, gender) × 3 (modeled behavior: salient category consistent, salient category inconsistent, new behavior) mixed-model ANOVA, with modeled behavior as a within-participants factor, was conducted.

Only a main effect for modeling emerged, $F(2, 120) = 57.74$, $p < .001$, partial $\eta^2 = .49$. Children imitated models of the same salient category as themselves—whether age or gender ($M = 3.67$, $SD = 1.64$)—significantly more than they imitated models of the salient-inconsistent category ($M = 2.73$, $SD = 1.45$), $t(61) = 2.57$, $p = .03$, and their imitation of both salient-consistent and salient-inconsistent modeling occurred significantly more than their performance of a new (or unseen) behavior ($M = 0.63$, $SD = 0.86$), $t(61) = 11.29$, $p < .001$, and $t(61) = 9.67$, $p < .001$ (salience consistent vs. new behavior and salience inconsistent vs. new behavior, respectively). Importantly, there was no interaction between sex of participant and modeled behavior, $F(2, 120) = 0.89$, nor between category salience (i.e., age vs. gender) and modeled behavior, $F(2, 120) = 0.20$. Boys and girls did not differ in their modeling responses to the age and gender salience manipulations nor in their amount of modeling in the gender-salient and age-salient conditions.

Memory for modeled behavior. Memory for models was recorded as either correct or incorrect according to salience-consistent or salience-inconsistent category membership. A 2 (sex of participant) × 2 (category salience: age, gender) × 2 (salience consistency: consistent, inconsistent) × 2 (recall: correct, incorrect) mixed-model ANOVA was performed, where salience consistency and recall were within-participants factors.

A main effect for salience consistency, $F(1, 60) = 107.30$, $p < .001$, partial $\eta^2 = .63$, was qualified by a Salience Consistency × Recall interaction, $F(1, 60) = 4.81$, $p = .03$, partial $\eta^2 = .07$. Although children's correct recall of salience-consistent ($M = 5.22$, $SD = 1.96$) and salience-inconsistent ($M = 5.75$, $SD = 1.51$) behaviors was greater than their incorrect recall of either (consistent: $M = 2.27$, $SD = 1.66$; inconsistent: $M = 1.81$, $SD = 1.48$), this difference was greater for incorrect recall of behaviors. Importantly, there was no effect for sex of participant or for category salience.

Discussion

The results of this study were clear. Depending on whether age or gender was made salient, children imitated models of their in-group on the salient dimension. That is, when age was made salient, girls chose to imitate the children (who in this case were boys) rather than the adults (who were women). When gender was salient, the girls imitated the women rather than the boys. Similarly, boys imitated men in the gender-salient condition, and they imitated girls in the age-salient condition. This last finding is particularly interesting, given boys' resistance to imitating females, demonstrated in Experiment 1 (see also Bussey & Bandura, 1984; Fagot, 1985b; Lamb & Roopnarine, 1979; Maccoby, 1980).

Consistent with Experiments 1 and 2, no sex differences were found in children's memory for behaviors. Boys and girls did not differ in the attention they paid to, or their memory for, the behaviors of models of either category. Similarly, there were no differences according to the salience of either gender or age. Indeed, children correctly remembered almost all behaviors in all conditions. Despite the salience manipulation occurring prior to children viewing the behaviors, they nevertheless paid attention to both sets of models and were able to recall the behaviors of each. It appears that children then chose to perform the behaviors in accordance with the self-categorization that had arisen from the salience manipulation. In the current study, the age and gender manipulations helped make the children perceptually ready for information consistent with, and motivated them to act in accordance with, those categories. These manipulations also provided a framework for the behaviors. Not only did children begin to think of themselves as either children (in the age salience conditions) or as boys or girls (in the gender salience conditions), the behaviors they saw in the video could be appropriately divided along these lines.

We contend that central to imitating behaviors consistent with this categorical division was the children's self-definitions as members of one of these categories. Although we had no explicit measures of categorization in the present study, the results are clear. When age was salient, it made sense for children to self-categorize as children; when gender was salient, it made sense to self-categorize as either boys or girls.

The salience manipulations in the present study provided a context for the participants' behavior. The sorting task provided a way of dividing their world —into males and females or into adults and children. This mirrored situations that young children face every day. Boys and girls are provided with, for example, different clothes to wear and different toys to play with and are even shown different ways to behave. Similarly, there are different expectations, and permissible behaviors, for children and adults. This can be illustrated with the responses of children in the current study when asked what children and grown-ups like to do. Some of the things that children liked to do were "play with toys" and "eat lollies." Among the things grown-ups "like" to do were "driving," "cook the dinner," "drink wine," and "clean things." Young children are well aware of these differences and that they may be expected to change their behavior according to the social context. A girl may be expected to be quieter and less active than her brother but noisier and more active than her parents.

Perhaps the most important implication of the results of the current study, however, concerns the importance of gender per se to 3- and 4-year-olds. Taken together, the results of these three experiments suggest that there is nothing inherently important about gender that is responsible for the strong display of gender-typed preferences, such as boys' and girls' preferences for toys, dress, playmates, and so forth (see LaFreniere et al., 1984; Maccoby & Jacklin, 1987; Moller & Serbin, 1996; Powlishta et al., 1993; Thorne, 1986). Rather, we suggest that this gender divide is, first, partially due to the important role that gender is given by others and, second, that young children are sensitive, and responsive, to this. Remarkably in the present study, children did not differ in their display of category-appropriate behavior in the different contexts. Boys imitated just as many behaviors of men, when gender was salient, as they did of girls, when age was salient. The current series of studies has shown that children could, and did, behave in accordance with the relevant categorizations of gender or age. Moreover, in this final study, children could, and did, behave in accordance with whichever of these categories was salient at the time, despite being presented with the exact same information (i.e., the behavior sequences in the video presentation) in the different conditions.

Importantly, there were no gender differences exhibited: Both the boys and the girls were similarly sensitive to the change in context, indicating that a different behavior was appropriate. The change in context provided a different meaning for those behaviors. Wearing a red hat was male behavior in one context but child behavior in another. Behavior that had previously been devoid of context was made contextually meaningful. Hence, the exact same behavior was interpreted differently depending on the social context in which it was presented.

Clearly then, young children are capable of adapting their (imitative) behaviors in ways that reflect variations in the contexts in which those behaviors occur. All the while, however, they appear to pay attention to an array of information provided to them. This is particularly the case with information pertaining to gender and age—characteristics that are frequently made salient in Australian society via explicit labeling and implicit use.

General Discussion

The present set of three experiments sought to examine preschoolers' understanding of categories, with a specific focus on gender in categorical terms. Given recent recognition of the importance of the categorization process as a guide to children's behavior, the experiments drew heavily on existing, and substantive, theories of social categorization. In utilizing SIT, we specifically drew on SCT, given its explicit integration of the personal and the social self into a single theoretical perspective. Although these theories were not conceived of as developmental theories, the psychological processes outlined in each have, in recent years, been increasingly applied to the developmental domain, particularly to work with children (e.g., Bennett, Lyons, Sani, & Barrett, 1998; Bigler et al., 1997; Powlishta, 1995b; Yee & Brown, 1992). Indeed, the approach put forward by each of these theories has been recognized as ideally suited for the integration of developmental and social psychology (Bennett & Sani, 2004) and plays a substantial role in Bigler and Liben's (2006, 2007) DIT.

Deriving from the basic assumption that gender development involves social categorical understanding, we examined the categorical nature of gender with a specific focus on children's imitation of observed others and the attention paid to information presented. In all three experiments, children's imitative preferences were consistent with the contextual variations presented, despite demonstrating equal recall of behaviors performed by members of both categorical in-groups and out-groups. It was suggested, therefore, that behavioral enactment is the result of a deliberate choice, made by the child, concerning appropriate behavior—behavioral choice that is not simply a function of a child's similarity to models. Rather, as demonstrated in Experiment 3, it appears that children's behavioral choices reflect their (contextually sensitive) self-categorizations.

That these findings were replicated across the studies, and applied equally to boys and girls, can also be seen as evidence against an innate sex differences perspective. Learning to be a girl or a boy does not follow some preordained path. Learning about gender involves an understanding of the categorical nature of gender—being one of many girls or boys—and an understanding that categories, themselves, are flexible, changeable, and context dependent. Learning about gender involves an integration of social categorical information into one's personal self-definition. These processes are complex, yet they are utilized from an early age.

The current studies also represent an important step toward specifying conditions under which children are more likely to use gender as a guide to their behavior and as evidence of suggestions made by Bigler and Liben (2006) that children's use of categorical information is impacted by societal rules and mores. We can, for example, intensify or diminish the likelihood of children choosing to enact behaviors consistent with gender expectations by manipulating the salience of gender or that of an alternative category such as age.

We recognize, however, that these findings occurred in an individual setting. Future research could well be directed at replicating these results in a group setting, although the potential practical and administrative problems of such research cannot be underestimated.

Although derived from a different theoretical framework, the results of the current studies, and the theoretical approach taken, should not be seen as completely divergent from contemporary theories of gender development. In light of recent debate on the topic (cf. Bandura & Bussey, 2004; Martin, Ruble, & Szkrybalo, 2002, 2004), the current work can be seen as providing additional, and complementary, support toward a contemporary integrated approach to gender development. Indeed, the incorporation of social psychological theory extends this work through the articulation of causal mechanisms involved in learning about gender. That these are the same processes involved in other intergroup, or categorical, experiences (e.g., stereotyping, prejudice; cf. Bigler & Liben, 2006, 2007) is consistent with the notion that gender does not constitute a "special" category and, as such, does not require its own exclusive theory. Conversely, future research focusing on domain-general psychological processes affecting children's understanding of their social world should continue to prove increasingly fruitful.

Children's Responses to Interparental Conflict: A Meta-Analysis of Their Associations With Child Adjustment

Kimberly A. Rhoades
Stony Brook University

A meta-analysis examined the relations between children's adjustment and children's cognitive, affective, behavioral, and physiological responses to interparental conflict. Studies included children between 5 and 19 years of age. Moderate effect sizes were found for the associations between cognitions and internalizing and externalizing behavior problems and self-esteem problems, negative affect and behavioral responses and internalizing behavior problems, and behavioral responses and self-esteem problems. Small to moderate effect sizes were found for the associations between cognitions and relational problems, negative affect and behavioral responses and externalizing behavior problems, and physiological reactions and internalizing and externalizing behavior problems. Effect sizes were, with 1 exception, larger for internalizing than for externalizing behavior problems. Age significantly moderated the majority of effect sizes.

The link between interparental conflict (IPC) and children's behavioral and emotional dysfunction is well established in both intact and divorced families (Amato & Keith, 1991; Buehler et al., 1997; Cummings & Davies, 1994, 2002; Davies & Cummings, 1994; Emery, 1982; Grych & Fincham, 2001; Ingoldsby, Shaw, Owens, & Winslow, 1999). However, not all children who witness IPC display behavior problems (Jouriles, Murphy, & O'Leary, 1989). More recent research efforts have focused on identifying the characteristics of children exposed to IPC, their coping responses to conflict, and contextual factors of IPC that may relate to adjustment problems (e.g., Cummings & Davies, 2002).

Ultimately, it is not the conflict itself but rather more proximal processes that must account for the relation between IPC and child behavior problems. Children's responses to IPC are one possible proximal variable. Such responses are indicators of how children process and make meaning of IPC in relation to their own needs, desires, and goals. Of course, children's responses to IPC are not the only variables relevant to the association between IPC and child dysfunction. This meta-analysis focuses on children's responses to conflict because: (a) children's own responses to IPC are most proximal to their own psychosocial and physical adjustment; (b) these responses provide an index of how children interpret and cope with IPC, which should ultimately mediate the relation between IPC and child adjustment; and (c) the literature on children's reactions to IPC is sufficiently large to warrant a systematic, quantitative review and provides an established theoretical background. This meta-analysis focuses on four broad categories of child responses to IPC: cognitions, emotional responses, behavioral responses, and physiological responses. These four categories represent the full spectrum of possible child responses to conflict; when children are exposed to IPC they can think, feel, act, and physiologically respond to the situation. The first three of these responses to IPC are included as mediating constructs in three major theoretical frameworks. We first explore empirical research on the relations between cognitive, affective, behavioral, and physiological responses to IPC and child adjustment, drawing on relevant theoretical frameworks when warranted. We then outline what is still unclear in the literature and how a meta-analysis can advance knowledge in the field.

Cognitions

Hostile internal representations of IPC are consistently and strongly related to children's behavior problems (Davies, Forman, Rasi, & Stevens, 2002). The emotional security hypothesis (Davies & Cummings, 1994) posits that children's reactions to IPC are

a function of the perceived implications of the conflict on the well-being of the family and have the goal of preserving and promoting the child's own emotional security. Thus, cognitions associated with threatened family security are likely to elicit fear and helplessness. These responses may, over time, become generalized responses to a variety of life events.

Additionally, researchers have found that cognitions of self-blame and threat are associated with internalizing behavior problems (Cummings, Davies, & Simpson, 1994; Grych, Fincham, Jouriles, & McDonald, 2000; Grych, Harold, & Miles, 2003; Grych, Seid, & Fincham, 1992; Jouriles, Spiller, Stephens, McDonald, & Swank, 2000; Kerig, 1998b; Rogers & Holmbeck, 1997). Consistent with the cognitive-contextual framework (Grych & Fincham, 1990; Grych et al., 2000), if children view their parents' conflicts as threatening to themselves or the family system or feel that they are unable to cope with the conflict they are likely to feel anxious and helpless. Likewise, if children feel that they are to blame for their parents' conflicts, they are likely to feel guilt, shame, and sadness (Grych & Fincham, 1990; Grych et al., 2000).

Children's cognitions could also be associated with aspects of development other than internalizing and externalizing behavior problems. For example, if children feel that they are to blame for their parents' conflict or that they are unable to cope with the conflict, they may be likely to have low self-esteem or self-worth (Rogers & Holmbeck, 1997). If children feel threatened by IPC, especially if they feel that the conflict may result in family dissolution or conflict spillover, their social relations within the family may be negatively influenced. Worry associated with threat cognitions or destructive family representations could also influence children's physical health through stress responses. Although we know relatively little about how children's cognitive responses to IPC influence their physical health, we do know that exposure to IPC is related to health problems (Gottman & Katz, 1989). Similarly, if children worry about how IPC may impact their family while they are in school, their academic progress may be influenced by their distraction. It is thus important to go beyond measures of internalizing and externalizing behavior problems when examining the possible impact of children's responses to IPC on child adjustment.

Affect

Child negative affect in response to IPC has also been investigated as a possible mediator of the relation between IPC and child adjustment. In response to IPC, sadness has been shown to be positively correlated with internalizing and externalizing behavior problems (Cummings, Goeke-Morey, & Papp, 2003). Fear has been shown to be positively correlated with internalizing behavior problems (Cummings et al., 2003; Crockenberg & Langrock, 2001). Anger, when coupled with paternal aggression, has been shown to be positively correlated with externalizing behavior problems in boys (Crockenberg & Langrock, 2001).

These findings are consistent with the cognitive-contextual framework (Grych & Fincham, 1990), the emotional security hypothesis (Cummings & Davies, 1994), and the specific emotions model (Crockenberg & Forgays, 1996; Crockenberg & Langrock, 2001). In the cognitive-contextual framework, emotions are conceptualized as primary responses to IPC, which then influence secondary, cognitive, processing of the event. Through its relation to cognitions, affect is thus viewed as a mediator of the relation between IPC and child adjustment. The emotional security hypothesis conceptualizes affect as an additional index of emotional security, which is ultimately related to child adjustment. Last, the specific emotions model posits that children's evaluations of IPC lead to affective reactions based on the children's expectations of specific goal attainment. These affective reactions are then theorized to relate to child internalizing and externalizing behavior problems.

Relations between affective reactions to IPC and child adjustment, however, have been inconsistent, especially for externalizing behavior problems. Although some authors find strong positive correlations between negative affect and internalizing (Davies & Cummings, 1998; Davies, Forman, et al., 2002) and externalizing (Ablow, 1997; Davies, Harold, et al., 2002) behavior problems, other authors have not found significant relations among these variables (Crockenberg & Langrock, 2001; El-Sheikh & Harger, 2001). It should be noted, however, that even nonsignificant correlations were positive; increased negative affect is certainly not associated with positive adjustment outcomes.

Behavioral Responses

Behavioral reactions to IPC are conceptualized as a final index of emotional security (Cummings & Davies, 1994) and are typically divided into involvement behaviors and avoidance behaviors. Involvement includes behaviors such as trying to break up the conflict or otherwise talking to or physically interacting with parents while they are arguing. Avoidance includes behaviors where children actively attempt to avoid their parents' conflict when they are aware of its occurrence. Behavioral reactions to IPC are not consistently positively related to adjustment problems. Although involvement in IPC is positively correlated with children's depression, low self-worth, anxiety, and hostility (O'Brien, Bahadur, Gee, Balto, & Erber, 1997; O'Brien, Margolin, & John, 1995), avoidance of IPC is negatively correlated with internalizing behavior problems in some studies (e.g., O'Brien et al., 1995) and positively correlated with internalizing behavior problems in other studies (e.g., Davies, Forman, et al., 2002). If a child avoids IPC and proceeds to ruminate over the conflict and or its implications for the family, he or she may be likely to develop internalizing behavior problems. Conversely, if a child avoids IPC by engaging in adaptive coping responses, such as distracting him- or herself with another positive activity, he or she might avoid the negative effects of IPC. Avoidance of IPC and externalizing behavior problems have not been found to be significantly correlated (see Davies, Forman, et al., 2002; O'Brien et al., 1995).

Physiological Responses

Physiological responses to IPC have been less frequently examined as possible mediators or moderators in the relation between IPC and child adjustment. Consistent with the emotional security hypothesis (Cummings & Davies, 1994), physiological responses to IPC may be indicators of the meaning placed on the conflict by the child. Thus, children's physiological responses to IPC may be associated with poor adjustment outcomes. Research has indicated that physiological responses to IPC are associated with adjustment outcomes (El-Sheikh, 2005; El-Sheikh, Harger, & Whitson, 2001; El-Sheikh & Whitson, 2006). Less is known, however, about the relative impact of physiological responses to IPC when compared to other child responses to IPC.

Age and Gender Effects

Inconsistent results have been found regarding the effects of gender on the relations between self-blame and threat cognitions and behavior problems. Some researchers find no gender differences (Grych et al., 1992; Jouriles et al., 2000). Others find that threat cognitions are a stronger predictor of dysfunction in boys, and self-blame cognitions are a stronger predictor of dysfunction in girls, even though boys and girls report similar rates of self-blame and threat cognitions (Cummings et al., 1994; Kerig, 1998b). Additionally, overall maladaptive cognitions were, in one study, a stronger predictor of externalizing behavior problems in boys and of internalizing behavior problems in girls (Kerig, 1998a).

Gender differences in the relations between negative affect and child adjustment have also been inconclusive. For example, El-Sheikh (2005) found that relations between self-reported anger and internalizing and externalizing behavior problems and self-reported sadness and externalizing behavior problems are stronger for girls than for boys. Additionally, Davies, Forman, et al. (2002) found gender moderation for links between cognitive and behavioral responses to IPC and maternal (but not child, paternal, or teacher) reports of child behavior problems. Other studies, however, have either failed to find gender differences (Cummings et al., 2006; Davies, Harold, et al., 2002) or have not directly examined the role of gender (Dukewich, 2001).

Child age could also be an important moderator of the relation between children's responses to IPC and their adjustment. Unfortunately, the role of child age is even less clear than that of gender. Most empirical studies use restricted age ranges or do not report analyses including child age as a predictor or covariate. Young children's behavior may be more highly influenced by primary processing (i.e., negative affective responses), whereas older children's behavior may be more highly influenced by secondary processing (i.e., cognitions; Grych & Fincham, 1990). We know that as children age, cognitions become less egocentric, less catastrophic about negative events, and more sophisticated (Harter, 1983; Leitenberg, Yost, & Carroll-Wilson, 1986; Piaget, 1932). Additionally, attributional cognitions become more highly correlated with depression as age increases (Nolen-Hoeksema, Girgus, & Seligman, 1992; Turner & Cole, 1994). Thus, as children age, they are less likely to make self-blaming (i.e., egocentric) or threat (i.e., catastrophic) attributions about events (Grych, 1998; Jouriles et al., 2000), although cognitions overall become more highly correlated with dysfunction.

Aims

The literature on children's responses to conflict is well developed and in many ways consistent. However, because no single study has included cognitive, affective, behavioral, and physiological responses to IPC in relation to broad child adjustment, it is difficult to interpret the relative importance or influence of each child response in relation to various adjustment indices. Similarly, no single study has included, or should be expected to include, all possible measures of child adjustment. By aggregating studies that include a variety of adjustment outcomes in relation to children's responses to IPC, we are able to make general conclusions about how these responses relate to adjustment as a whole. We are also then able to compare the relations between child responses to IPC and various measures of adjustment. The literature has also been unable to make conclusive statements about the possible moderating role of age or gender in the relations between children's responses to IPC and child adjustment. If the major theories are designed to apply to all children, then we should expect that all relevant responses to IPC are related to child adjustment for each age group and for both boys and girls. If this is not true, we may need to adjust our theories to reflect that processes may differ between older and younger children or boys and girls.

A meta-analysis is important at this time to (a) quantify, in one report, the past 15 or so years of research on the relation between children's responses to IPC and child adjustment; (b) compare the relative impact of each of these responses to IPC on child adjustment; (c) reduce uncertainty about gender effects in the relations between children's responses to IPC and adjustment; and (d) examine age effects in the relations between children's responses to IPC and adjustment. It is important for researchers, clinicians, and policy makers to have consolidated, easily accessible information about responses to IPC that are likely to be more or less deleterious to child development. It is similarly important for them to know if boys or girls or certain age groups are more or less likely to be negatively influenced by various responses to IPC.

Consequently, the first goal of the meta-analysis is to evaluate the research support for the relations between child adjustment and children's cognitive, affective, behavioral, and physiological responses to IPC. In relation to this goal, the relative effect sizes for the four constructs are compared with the goal of more fully understanding which, if any, of the constructs are more or less related to child adjustment. The second goal of the meta-analysis is to examine possible differences in the relations between children's responses to IPC and different types of adjustment difficulties. For instance, are children's responses to IPC more strongly related to internalizing behavior problems or externalizing behavior problems? The final goal is to evaluate the possible moderating effects of child age and gender for all significant relations between children's responses to IPC and child adjustment.

Method

To identify relevant studies for inclusion in the meta-analysis, computerized searches of five electronic databases—PsychInfo, PubMed, Dissertation Abstracts International, ERIC, and Sociological Abstracts—were conducted. Keywords used in the computerized search included interparent* conflict*, parent* conflict*, interparent* disagreement*, parent* disagreement*, child rearing disagreement*, child related disagreement*, child rearing conflict, child related conflict, behav* adjustment, coping, appraisal*, cognition*, reaction*, buffering factors, respon*, emotional response, behavioral response, child appraisal, adjustment, externalizing behavior problems, internalizing behavior problems, resilience, moderators, mediators, social development, domestic violence, and intimate partner violence (* indicates that any permutations of the word stem were retrieved). These keywords were selected based on a desire to include studies assessing a variety of IPC types, child responses to IPC, and adjustment variables in the meta-analysis. Studies including conflict about marital relations, children or childrearing practices, daily activities, and domestic violence were all included. No study was excluded based on type of IPC, type of child response to IPC, or type of adjustment variable. The search was limited to English language articles.

This initial search yielded a total of 7,422 studies (with expected overlap among the databases). To be included in the meta-analysis, each study met five criteria: (a) the study was published in English, (b) the study included at least one measure of child adjustment, and (c) the study included at least one measure of children's cognitive, emotional, behavioral, or physiological responses to IPC. Closer examination of the titles and abstracts of studies resulted in 130 studies that could possibly meet inclusion criteria. These studies were retrieved and more closely inspected. The reference lists of the retrieved articles, as well as all relevant meta-analyses, literature reviews, and books were then examined to identify any additional studies for inclusion. Nine journals likely to publish articles in this area:—*Journal of Family Psychology*, *Child Development*, *Journal of Abnormal Child Psychology*, *Journal of Marriage and Family*, *Developmental Psychology*, *Parenting: Science and Practice*, *Journal of Divorce and Remarriage*, *Journal of Clinical Child and Adolescent Psychology*, and *Journal of Child Psychology and Psychiatry*—were hand searched. This process yielded four additional studies. The above searches were conducted in September 2007. Finally, experts in the field were contacted to identify any relevant in press or unpublished studies. Experts in the field were identified as those researchers who were first authors on more than one published article in the area of children's responses to IPC and child adjustment. These 11 researchers were contacted once via e-mail. The combined literature search resulted in a total of 142 possibly relevant studies.

Of the 142 studies initially retrieved for inclusion in the meta-analysis, 17 did not include measures of child adjustment, 19 did not include measures of children's responses to IPC, 18 studies did not include the necessary statistical values, 7 articles included duplicate samples, and 16 articles were purely theoretical or reviews. The authors of the 18 studies that did not report the necessary statistical values were contacted via e-mail. Two authors responded with the necessary information. This resulted in a final group of 71 studies that were included in the current meta-analysis. These 71 studies came from 67 articles, with 4 articles containing two studies or data sets. The majority of included studies (52) were published journal articles; the remaining 19 were dissertations. Of these 71 studies, 50 included measures of cognitions, 18 included measures of negative affect, 23 included measures of behavioral reactions in response to IPC, and 6 studies included measures of physiological responses to IPC. Only 4 studies separated negative affect into specific emotions (Crockenberg & Langrock, 2001; Cummings et al., 2003; El-Sheikh, 2005; Harold, Shelton, Goeke-Morey, & Cummings, 2004). Because of this, analyses involving negative affect used composite measures of negative affect, averaging effect sizes for fear, anger, and sadness when they were reported separately. Cognitions were analyzed as a unified construct and separately for self-blame and threat cognitions. Behavioral reactions were analyzed both as a unified construct and separately for active avoidance of and involvement in IPC. Because of the heterogeneity of physiological responses in the literature, physiological responses to IPC could only be analyzed as a unified construct. Two of the included studies measured skin conductance, 1 measured skin conductance and heart rate, 1 measured cortisol reactivity, and 2 measured vagal regulation. Attempts were made to include the higher order construct of emotional security in the analyses. However, only two articles included the necessary zero-order correlations between overall emotional security and child adjustment. All articles that included relations between cognitive, affective, and behavioral components of emotional security were included in the review. Adjustment variables in the review include: internalizing and externalizing behavior problems, self-esteem problems, relational problems, academic or cognitive problems, physical health problems, emotion dysregulation, and poor self-esteem or self-worth. In most cases, there were not enough studies reporting a particular adjustment variable (the exceptions being internalizing and externalizing behavior problems, poor self-esteem, and relational problems) to separately meta-analyze the results. In these cases, the effect sizes for these adjustment variables were only included in the overall adjustment analyses.

Nine studies that included measures of cognitions reported results separately by gender. Thus, these studies were analyzed with both the entire sample and separately by gender. Because only a small number of studies reported results separately by gender, analyses for negative affect, behavioral reactions, and physiological responses were only run with the whole samples.

A very small number of studies that met inclusion criteria included longitudinal data. For consistency across studies, when the article included both cross-sectional and longitudinal data, the cross-sectional data were aggregated with the other cross-sectional studies. Because of the paucity of longitudinal data meeting inclusion criteria, longitudinal results were not aggregated but are later described in relation to aggregate cross-sectional findings.

Study Coding

Each of the 71 articles included in the meta-analysis were coded. Coded study characteristics included the type of publication, publication year, first author name, type of data collection method, mean child age, percentage of male children, percent minority and dominant minority group, clinical status of the population, percentage of married or cohabitating parents, and mean family income. Twenty-five percent of the articles were coded by an independent coder to determine reliability. Intraclass correlation coefficients for continuously coded variables ranged from .93 to 1.00. Cohen's kappa for categorically coded variables ranged from .88 to 1.00.

Results

All results are for weighted fixed effects analyses. A fixed effects model assumes that the effect size obtained in a study estimates the population effect sizes, with random error that derives solely from participant sampling (Lipsey & Wilson, 2001). This model is additionally used when one assumes that any heterogeneity in effect sizes is due to systematic differences between studies that can be modeled. Aggregate effect size and moderator analyses were conducted using SPSS Macros for Meta-Analysis Version 2005 (Wilson, 2005). After weighting for sample size, each effect size is given in correlation coefficient metric, ranging from −1 to +1. Effect sizes are positive when a higher degree of negative cognitions, negative affect, behavioral responses to IPC, or physiological responses to IPC was associated with more adjustment problems. Effect sizes are categorized as large, medium, and small if values were about equal to the following values: large = .40, medium = .25, and small = .10 (Lipsey & Wilson, 2001). For each significant aggregate effect size, two fixed effects analogue to regression analyses with age and methodological quality as potential moderating variables were conducted. Methodological quality was continuously scored with studies receiving 1 point each for using: (a) daily diary reports, (b) audio or video vignettes of IPC, and (c) observation of child behavior problems and/or child responses to IPC. Methodological quality ranged from 0 to 3 points with a mean of 0.18. For each significant effect size, fixed effects analogues to analyses of variance (ANOVAs) with publication status and dichotomous child age (above or below the mean) as the moderating variables were conducted. Additionally, for each significant aggregate effect size, the fail-safe *N* (Rosenthal, 1979) was computed. The fail-safe *N* estimates the number of studies reporting null findings needed to reduce the aggregate effect sizes to negligible levels. All fail-safe *N* analyses were conducted using the formula proposed by Orwin (1983). For this analysis, the critical effect size value was set at .01, representing a negligible effect size. Effect sizes were aggregated separately if at least three studies included the measure of child response to IPC or adjustment. Composite measures of overall maladaptive cognitions and overall behavioral responses to IPC were created to include all cognitive and behavioral variables, including those that were not reported in at least three studies. Similarly, overall adjustment indices were created to include all adjustment variables, including those that were not reported in at least three studies.

Descriptives

For this sample of 71 studies, the mean child age was 10.61 years (*SD* = 2.84), with a range of 5.0–19.3 years. Minority percentage ranged from 0% to 100% with a mean of 27.72% (*SD* = 23.90) minority participants. Of the studies that included minority participants, the dominant minority group was African American in 59.2% of the studies and Hispanic in 11.3% of the studies. The remaining studies including minority participants listed another minority group as the largest minority group or did not provide this information. Between 0% and 100% of the adult participants were married or cohabitating, with a mean of 92.46% (*SD* = 16.60). The mean yearly family income was $39,763.65 (*SD* = $18,781.95), with a range of $6,684–$88,000. About 74.6% of the studies had about equal numbers of boy and girl children, 11.3% had between 5% and 45% male children, 8.5% of the studies had 55% to 95% male children, and 1.4% had more than 95% male children. The remaining studies did not report this information. Forty-four percent of the studies used questionnaires as the sole data collection method, 7% used interviews as the sole data collection method, and 49% of the studies used a combination of methods.

Cognitions and Adjustment Problems

Fifty studies included information on the relations among cognitions about IPC and children's adjustment problems (Table 1). These studies included 10,364 participants, with a mean of 207.28 participants per study. Results are reported both for overall maladaptive cognitions (including self-blame cognitions, threat cognitions, control cognitions, and coping efficacy) and separately by self-blame and threat cognitions. The overall weighted aggregate effect size including all studies for the relation between cognitions and adjustment problems was $r = .18$, $p < .001$. Each of the more specific effect sizes was significant ($p < .001$), and most weighted aggregate effect sizes were medium-large (see Table 1 for values). The fail-safe *N* for these analyses ranged between 52 and 1,485. Each fail-safe *N* exceeded suggested minimum values (Rosenthal, 1984).

Nine of the 50 studies reported cognition results separately by gender. The 9 studies included 1,507 participants, with a mean of 167.44 participants per study. All weighted aggregate effect sizes were significantly ($p < .001$) different from zero. Most weighted aggregate effect sizes were of medium strength (see Table 1 for values). The fail-safe *N* indicated that between 152 and 384 unpublished studies with null results would be needed to reduce the aggregate effect sizes to negligible levels. Each fail-safe *N* exceeded suggested minimum values (Rosenthal, 1984).

Negative Affect and Adjustment Problems

Eighteen studies were included that measured relations between negative affect and adjustment problems (Table 2). These studies contained 3,538 total participants, with a mean of 196.56 participants per study. The overall weighted aggregate effect size including all studies for the relation between negative affect and adjustment problems was $r = .14$, $p < .001$. Each of the more specific weighted aggregate effect

	Threat and Ext	6	.25 (0.21)***	.18 – .31	7.04	Yes

Note. Cog = overall cognitions; SB = self-blame cognitions; Threat = threat cognitions; Adj = overall adjustment problems; Rel = relationship problems; Self = self-esteem problems; Int = internalizing behavior problems; Ext = externalizing behavior problems; Effect Size *r* = weighted aggregate effect size (correlation); *SD* = standard deviation of the weighted aggregate effect size; 95% CI = 95% confidence interval for the weighted effect size; Age Moderation = Is age a significant moderator of the effect size?
$^{*}p < .05$. $^{***}p < .001$.

sizes was significantly different ($p < .001$) from zero. Most weighted aggregate effect sizes were small to medium-large (see Table 2 for values). The fail-safe *N* indicated that between 224 and 480 unpublished null studies would be needed to reduce the aggregate effect sizes to negligible levels. Each fail-safe *N* exceeded suggested minimum values (Rosenthal, 1984).

Behavioral Responses to IPC and Adjustment Problems

Twenty-two studies were included that investigated the relations between behavioral responses to IPC and adjustment problems (Table 2). These studies included 5,618 total participants, with a mean of 255.36 participants per study. The overall weighted aggregate effect size including all studies for the relation between behavioral responses and adjustment problems was $r = .19$, $p < .001$. Each of the more specific weighted aggregate effect sizes, except one, was significantly ($p < .001$) different from zero. Weighted aggregate effect sizes were in the small–medium range (see Table 2 for values). The fail-safe *N* for these significant findings indicated that between 63 and 506 unpublished null findings would be required to reduce the aggregate effect sizes to negligible levels. Each fail-safe *N* exceeded suggested minimum values (Rosenthal, 1984). A nonsignificant ($p = .07$) weighted aggregate effect size was found for the relation between avoidance of IPC and externalizing behavior problems.

Physiological Responses to IPC and Behavior Problems

Six studies were included that investigated the relations among physiological responses to IPC and adjustment problems. These studies included 768 participants, with a mean of 128 participants per study. The overall weighted aggregate effect size including all studies for the relation between physiological responses and adjustment problems was $r = .12$, $p < .001$. Each of the more specific weighted aggregate effect sizes was significantly ($p < .001$) different from zero, and small in strength (see Table 2 for values). The fail-safe *N* indicated that between 60 and 78 studies with null findings would be required to reduce the aggregate effect sizes to negligible

levels. Each fail-safe *N* exceeded suggested minimum values (Rosenthal, 1984).

Effect Size Comparisons

Using r to z transformations, effect sizes for the relations between each of the four constructs and adjustment problems were compared. Aggregate effect sizes for the relations between cognitions and negative affect and internalizing behavior problems were significantly larger ($p < .05$) than those for behavioral and physiological responses to IPC and internalizing behavior problems (with one exception of negative affect and involvement in IPC). Aggregate effect sizes for the relations between cognitions and externalizing behavior problems were significantly larger ($p < .01$) than those for negative affect, behavioral responses, and physiological responses to IPC and externalizing behavior problems. Aggregate effect sizes for the relation between cognitions and self-esteem problems were significantly ($p < .001$) larger than the relation between behavioral responses to IPC and self-esteem problems. For overall adjustment, relations were significantly ($p < .001$) larger for cognitions and behavioral responses to IPC than for physiological responses to IPC.

Differences for Internalizing Compared to Externalizing Behavior Problems

Using r to z transformations, effect sizes for the relations between children's responses to IPC and internalizing behavior problems were compared to the effect sizes for the relations between children's responses to IPC and externalizing behavior problems. Other adjustment indices were not examined due to the small number of studies representing each adjustment outcome. With the exception of physiological responses, all effect sizes for the combined samples of boys and girls were larger for relations with internalizing behavior problems than for relations with externalizing behavior problems (all $p < .001$).

Age and Gender Moderation

For all significant effect sizes, analogue to regression moderation analyses were conducted with child age entered as the moderator. Child age was a significant moderator of 22 of 34 relations between child responses to IPC and adjustment problems (see Tables 1 and 2). In all instances, effect sizes were larger for older children than for younger children. To examine whether any of the effect sizes were nonsignificant for older children or younger children, analogue to ANOVA analyses were conducted with dichotomous child age as the moderator. Older children were defined as those at or above the mean of 10.61; younger children were defined as those below the mean of 10.61. Overall moderation results were equivalent to the previous regression results. Aggregate effect sizes were nonsignificant for the relations between overall cognitions and internalizing and externalizing behavior problems for younger girls, self-blame and externalizing behavior problems for younger boys, threat and internalizing behavior problems for younger girls, and threat and externalizing behavior problems for younger girls and younger boys ($p > .05$).

For those studies that reported effect sizes separately for boys and girls, effect sizes for the relations between self-blame and threat cognitions and adjustment for boys were compared to those for girls using r to z transformations. No significant differences were found (all $p > .05$).

Publication Status and Quality Moderation

For all significant effect sizes, analogues to ANOVA were conducted with publication status and methodological quality entered as moderators. Publication status moderated the magnitudes of the relations between 14 of 34 significant aggregate effect sizes (all *ps* $< .05$). In all cases, effect sizes were larger for published studies than for unpublished studies. Study quality moderated the magnitudes of the effect sizes for 11 of 34 significant aggregate effect sizes (all *ps* $<$ .05). Higher quality studies, for these relations, reported smaller effect sizes than lower quality studies.

Additional Analyses

Because the relations among children's reactions to IPC and their adjustment problems might be confounded with the amount of exposure children have to conflict, partial correlations controlling for the amount of IPC were computed for those studies that reported the necessary statistical values. The subsequent analyses are based on between 5 and 22 studies depending on the relation being analyzed. Partial aggregate effect sizes were significant for all relations with two exceptions: avoidance of IPC and internalizing and externalizing behavior problems (see Table 3). Bivariate aggregate effect sizes were significantly larger ($p < .05$) than partial aggregate effect sizes for all relations with the following exceptions: negative affect and externalizing behavior problems, avoidance and externalizing behavior problems, and involvement and externalizing behavior problems.

Although there were not enough longitudinal studies that met inclusion criteria to aggregate results across studies, bivariate correlations were extracted from these studies for comparison with cross-sectional aggregate results. Due to the small number of studies represented by these results, caution is urged in their interpretation. Two longitudinal studies provided bivariate longitudinal correlations among cognitions and adjustment problems, four studies (two within the same article) provided longitudinal correlations among negative affect and adjustment problems, five studies (two within the same article) provided longitudinal correlations among behavioral responses to IPC and adjustment problems, and three studies provided longitudinal correlations among physiological reactivity and adjustment problems. Longitudinal correlations were significantly lower than cross-sectional correlations for relations among cognitions and negative affect and internalizing behavior problems ($p < .01$).

Table 3
Partial Aggregate Effect Sizes Controlling for Amount of Interparental Conflict

Constructs	*N* studies	Effect size *r*	95% CI	Bivariate comparison

$^{*}p < .05$. $^{**}p < .01$. $^{***}p < .001$.

Discussion

The first goal of the meta-analysis was to evaluate and compare the research support for the relations among children's cognitions, negative affect, behavioral, and physiological reactions to IPC and their adjustment. Most aggregate effect sizes were significantly different from 0. Overall, the pattern of data implies that all four response constructs are related to child adjustment, although the relations appear stronger for cognitions and negative affect than for behavioral and physiological reactions to conflict.

Only one aggregate bivariate effect size was nonsignificant for the relation between avoidance and externalizing behavior problems. Avoidance is exclusively associated with internalizing behavior problems. If children are ruminating or worrying about the conflict during their avoidance, they may be likely to develop internalizing behavior problems. Alternatively, children who report more internalizing behavior problems may be more likely to avoid IPC in general, whereas children reporting externalizing behavior problems may be less likely to actively avoid IPC.

The second goal of the meta-analysis was to examine differences in the relations among children's responses to IPC and different types of adjustment problems. With the exception of involvement in IPC, relations between children's responses to IPC and internalizing behavior problems were larger than relations with externalizing behavior problems. If children use maladaptive coping strategies in response to IPC, they may be particularly vulnerable to using these same or similar maladaptive coping skills whenever they are confronted with difficult life circumstances. Inability to cope with various life stressors may make children particularly at risk for internalizing behavior problems. Because exposure to IPC and externalizing behavior problems are clearly associated, we need to know more about which, if any, child responses to IPC are more strongly or uniquely predictive of externalizing behavior problems. Although aggressive responses to IPC are related to general externalizing behavior problems (Cummings, Goeke-Morey, & Papp, 2004), the direction of this association is unclear.

The final goal of the meta-analysis was to examine the effects of age and gender on the relations between children's responses to IPC and their adjustment problems. Gender differences could only be explored for the relations among cognitions and internalizing and externalizing behavior problems. Interestingly, no significant differences were found between the aggregate effect sizes for girls and those for boys. This is consistent with previous studies that have failed to find gender differences in the relations between self-blame and threat cognitions and behavior problems (Grych et al., 1992; Jouriles et al., 2000). This does not imply that boys and girls are necessarily similarly susceptible to maladaptive cognitions; rather, these results imply that gender does not significantly influence how those cognitions are related to internalizing or externalizing behavior problems.

Age was found to be a significant moderator of the majority significant aggregate effect sizes. In each case, older children showed stronger associations between the two constructs than did younger children. Negative responses to IPC may be more likely to, over repeated experiences, become a characteristic response pattern to a variety of life events, resulting in more generalized internalizing or externalizing behavior problems. Effect sizes were nonsignificant for younger children for six of the relations between responses to IPC and adjustment. It may be that children younger than about age 10 lack the cognitive sophistication necessary for effectively generating and processing maladaptive cognitions about IPC. Younger children may also generate these cognitions while conflict is occurring but not continue to process them after the conflict resolves. Possibly, extended rumination about IPC increases one's risk of developing more generalized persistent behavior problems. Also, younger children have not had as much opportunity to witness IPC as older children. In line with the sensitization hypothesis (Davies, Myers, Cummings, & Heindel, 1999), conflict exposure may influence the relation among children's responses to IPC and their behavior problems. Although IPC exposure certainly influences child adjustment, aggregate partial correlations illustrate that children's responses to IPC (with the exception of avoidance) are significantly related to their adjustment even when exposure to IPC is statistically controlled. Particularly, in light of the nonsignificant effect sizes for the relations among some child responses to IPC and children's behavior problems for children under about 10 years, future studies should attempt to explain how and why relations between children's responses to IPC and their adjustment differ for elementary age versus adolescent children.

Result interpretation is limited by uncertainty about the directionality of the effects. Theories of the relations between children's responses to IPC and child adjustment have explained the process as being one in which children's reactions to IPC lead to child behavior problems (Davies & Cummings, 1994; Grych & Fincham, 1990). However, children's behavior problems could also influence their reactions to IPC. Children with internalizing behavior problems may be more likely to blame themselves for the conflict or feel threatened, anxious, fearful, or sad about the conflict, and be likely to avoid the conflict. Negative affect has been found to predict avoidant coping and be related to avoidance goals (Blackburn, Johnston, Blampied, Popp, & Kallen, 2006; Sideridis, 2005). Avoidance, then, could be the result of generalized internalizing behavior problems that manifest as fear or sadness in the presence of IPC than an antecedent of internalizing behavior problems.

Externalizing behavior problems could also influence children's reactions to IPC. For example, if children are generally aggressive, they are probably more likely to involve themselves in their parents' conflict than nonaggressive children. Externalizing behavior problems are indeed related to both aggressive responding to IPC in the home, and the endorsement of aggressive responses to IPC in laboratory analogue tasks (Cummings et al., 2004). Additionally, aggressive children are more likely to make hostile attributions (i.e., threat cognitions) than nonaggressive children (Dodge & Somberg, 1987). The relation between children's responses to IPC and their adjustment problems could thus be influenced by children's preexisting internalizing or externalizing behavior problems.

Longitudinal results, however, indicate that children's responses to IPC predict later behavior problems. For example, Cummings et al. (2006) found that IPC at Time 1 predicts 'children's responses to IPC at Time 2, which predicts internalizing and externalizing behavior problems at Time 3. Additionally, Schermerhorn, Cummings, DeCarlo, and Davies (2007) found that although behavioral dysregulation in response to IPC was positively associated with subsequent internalizing and externalizing behavior problems, internalizing and externalizing behavior problems were not significantly associated with later behavioral dysregulation. In other research (Grych et al., 2003; Schermerhorn, Cummings, & Davies, 2005), bidirectional effects are suggested. Although causality can only be definitively determined through experimental studies, carefully crafted longitudinal studies with multiple time points allow one to make strong inferences about causality and allows for the examination of the development of these processes. Harold et al. (2004) made advantageous use of this type of longitudinal design and were able to make causal assertions about the mediational role of cognitive, affective, and behavioral responses to IPC. In a positive move, longitudinal studies on this topic are becoming increasingly more common. It would be advantageous, however, to see longitudinal studies including all four types of child responses to IPC, and multiple measures of child adjustment, as well as additional analogue experimental studies.

Limitations of the meta-analysis should be noted. First, most of the included studies used questionnaires or structured interviews as the sole method of data collection. The accuracy with which responses on questionnaires or during interviews capture children's responses to IPC is unclear. Self-report methodology may overestimate true effect sizes, as studies using observation, daily diaries, and audio or video vignettes resulted in smaller aggregate effect sizes than studies using questionnaires. Although a small number of included studies used diary methods (see Cummings et al., 2003) or behavioral observations (see Davies & Cummings, 1998; El-Sheikh, 2005) to measure either children's responses to IPC or behavior problems, future studies could be improved by including these methods of data collection more frequently or by devising innovative methods for more accurately assessing children's responses to IPC. An additional limitation related to self-report methodology is that often children's responses to IPC and their behavior problems are reported by the same informant. This concern has been partially addressed by the nature of the literature. In many included reports, children's responses to IPC were reported by children, although their behavior problems were reported by their parents. Because this was not the case for all studies, and it could be argued that children's reports of internalizing behavior problems should always be used in lieu of parents' reports of these problems, the limitation cannot be completely addressed.

Sixteen studies were excluded because the authors did not include the necessary statistical values. The fail-safe *N*, however, indicates that even if these studies had null effect sizes, the results would remain significant. Higher order child responses to IPC could not be included in the meta-analysis due to statistical limitations. When higher order variables were included, relations between the latent variable and child adjustment were typically indexed multivariately. Because these studies controlled for different variables, we were unable to statistically aggregate findings related to higher order constructs.

A final limitation is that this meta-analysis focused solely on the relations among children's responses to IPC and child adjustment. This focus omitted studies that measured children's responses to IPC but did not include measures of child adjustment. It also omitted studies that focused on the relation between IPC and child adjustment but that did not include measures of children's responses to IPC. Ultimately, this meta-analysis was not designed to be a comprehensive review of all possible mediators or moderators of the relation between IPC and child adjustment, but rather a more focused review of the relations between one particular type of mediator, children's responses to IPC, and child adjustment.

Overall, the pattern of results indicates that children's cognitive, affective, behavioral, and physiological responses to IPC are moderately related to child adjustment. The results of this meta-analysis are informative in light of current theory about the mechanisms by which IPC influences children's behavior problems. It is clear that most child responses to IPC are significantly related to child adjustment. These results remain significant for all responses except avoidance even after controlling for conflict exposure. Results indicate that the cognitive-contextual framework, the emotional security hypothesis, and the specific emotions model all have something to contribute in explaining the relation between IPC and children's behavior problems. Because the cognitive-contextual framework and the emotional security hypothesis differ primarily by how they propose child responses to conflict influence adjustment and both, although to varying degrees, include cognitions, affect, and behavior in their models, it is difficult to evaluate which framework best describes the data. Cognitions and negative affect are more strongly related to adjustment problems than behavioral or physiological responses. However, all three theories include these two responses to IPC, making it difficult to argue for the supremacy of one theory over another. Because these theories include very similar constructs, it may be advantageous to further investigate the integration of the theories. Future studies should continue to concentrate on how each of these theories can inform one another and consider how different types of child responses may interact together in predicting child behavior problems.

Children Who Read Words Accurately Despite Language Impairment: Who Are They and How Do They Do It? Dorothy Bishop, David McDonald, Sarah Bird, and Marianna Hayiou-Thomas.

Multiple Child Care Arrangements and Young Children's Behavioral Outcomes, Taryn Morrissey.

Boys Will Be Boys; Cows Will Be Cows: Children's Essentialist Reasoning About Gender Categories and Animal Species, Marianne G. Taylor, Marjorie Rhodes, and Susan Gelman.

Social Perception in Infancy: A Near Infrared Spectroscopy Study, Sarah Lloyd-Fox, Anna Blasi, Agnes Volein, Nick Everdell, Clare E Elwell, and Mark H. Johnson.

Probing the Neural Correlates of Anticipated Peer Evaluation in Adolescence, Amanda E. Guyer, Erin B. McClure-Tone, Nina D. Shiffrin, Daniel S. Pine, and Eric E. Nelson.

The Effects of Early Experience on Face Recognition: An Event-Related Potential Study of Institutionalized Children in Romania, Margaret C. Moulson, Alissa Westerlund, and Charles A. Nelson.

The Cognitive and Behavioral Characteristics of Children With Low Working Memory, Tracy Alloway, Susan Gathercole, Hannah Kirkwood, and Jullian Elliott.

Editorial Acknowledgments

Each calendar year we use the closing pages of the volume to offer thanks to the many people who help to make *Child Development* a success. This year's acknowledgments carry particular import because they are the final ones of my editorship, and thus it is a time to reflect not only on the preceding year, but also on my entire six-year editorial term.

As usual, I begin by conveying my gratitude to the colleagues named on the cover who have served as Associate Editors during the past year. I would like to single out for special recognition the six colleagues who began by the first issue of 2003 and then stayed with the journal until the very end of my term. Joe Allen, Marv Daehler, Kathy Hirsh-Pasek, Pat Miller, Sharon Nelson-Le Gall, and Paul Quinn have been editorial soul mates during the last six years, offering not only their superb scholarship, but also their steadfast support. I will always remain deeply grateful. Also essential to the review process are the Consulting Editors – whose names appear inside the cover—and the ad hoc reviewers—whose names are listed below. The editors, authors, and the discipline at large have benefited from their expert and dedicated work.

The Editorial Office in Ann Arbor also deserves our deep thanks. In particular, Detra Davis, the Managing Editor, has provided constant professional support, patience, and ever-present good cheer to editors, reviewers, and authors alike. Kaitlin (Kate) MacKenzie has continued to serve professionally as the Editorial Assistant. Also deserving special thanks are other key SRCD staff—Andrea Browning, Susan Lennon, and Mary Ann McCabe—and our Wiley-Blackwell production editor, Teresa Huang. Together they have made the operation of *Child Development* smooth and enjoyable. We thank all who have contributed during the last year and, indeed, during our entire editorial term.

CLINICAL PSYCHOLOGY

SCIENCE AND PRACTICE

CLINICAL PSYCHOLOGY:
SCIENCE AND PRACTICE

Edited by
PHILIP C. KENDALL

Published on behalf of the Society of Clinical Psychology, Division 12 of the American Psychological Association

Clinical Psychology: Science and Practice presents cutting-edge developments in the science and practice of clinical psychology by publishing scholarly topical reviews of research, theory, and application to diverse areas of the field, including assessment, intervention, service delivery, and professional issues.

Notice to Contributors

Child Development publishes empirical, theoretical, review, applied, and policy articles reporting research on child development. Published by the interdisciplinary Society for Research in Child Development (SRCD), the journal welcomes relevant submissions from all disciplines. Further information is available at http://www.srcd.org/cd.html.

Types of Articles

Child Development considers manuscripts in formats described below. Inquiries concerning alternative formats should be addressed to the Editor prior to submission. All submissions are expected to be no more than 40 manuscript pages, including tables, references, and figures (but excluding appendices). Authors should provide a justification if the submission is substantially longer. Unless the editor finds that justification compelling, the submission will be returned to the author for shortening prior to editorial review.

Empirical articles comprise the major portion of the journal. To be accepted, empirical articles must be judged as being high in scientific quality, contributing to the empirical base of child development, and having important theoretical, practical, or interdisciplinary implications. Reports of multiple studies, methods, or settings are encouraged, but single-study reports are also considered. Empirical articles will thus vary considerably in length, but should be no longer than 40 manuscript pages; text and graphics should be as concise as material permits. All modes of empirical research are welcome.

Empirical reports are reserved for short cutting-edge empirical papers that are no longer than 4,000 words in length (including text, tables, footnotes, appendices), which advance research and knowledge in an area through noteworthy findings and/or new methods. For manuscripts that require longer descriptions of methods and results, authors should use the Empirical article format.

Reviews focus on past empirical and/or on conceptual and theoretical work. They are expected to synthesize or evaluate a topic or issue relevant to child development, should appeal to a broad audience, and may be followed by a small number of solicited commentaries.

Essays describe original concepts, methods, trends, applications, and theories; these may also be accompanied by solicited commentaries.

Child Development and … are articles that provide readers with tutorials about some new concept or academic specialty pertinent to research in child development. These papers should review the major definitions, methods, and findings of the concept or specialty and discuss past or potential links to child development.

From another perspective is a format in which papers on a focal topic, written by different authors, are published simultaneously. Papers represent diverse perspectives (e.g., authors whose work represents different populations; different disciplines; different theories, methods, or analytic tools). In some cases, calls for submissions on particular topics will be disseminated through SRCD (via e-mail or SRCD publications), and submissions will undergo normal editorial review. In some cases, a submitted manuscript (e.g., an empirical article) may be selected as a lead article for this format, with invited commentaries providing additional perspectives. The editors also welcome suggestions from readers for topics for this format.

Manuscript Submission

Child Development invites for consideration manuscripts that are neither identical to nor substantially similar to work published or under review elsewhere. In the submission cover letter, please provide details about other published or submitted papers having substantial overlap (including data sets) with the new CD submission to enable editors to judge whether the new submission is sufficiently distinct from other work to warrant consideration. Please note if the paper is posted on a website, see http://www. srcd.org/webposting.html. Editors retain the right to reject manuscripts that do not meet established ethical standards for research or dissemination.

Manuscripts should be submitted electronically to the Child Development Online Submission Site at www.srcd.org/CDsubmit/ as a Word or WordPerfect file. Please also submit a cover letter that contains the name(s) of the author(s) and affiliation(s), and the street address, telephone, fax, and electronic mail address of the corresponding author. A corresponding author's submission to *Child Development* implies that all coauthors have agreed to the content and form of the manuscript and that the ethical standards of SRCD have been followed (see the *Child Development* website or pp. 283–284 of the 2000 SRCD Directory). Any financial interest or conflict of interest must be explained to the Editor in the cover letter. The corresponding author is responsible for informing all coauthors, in a timely manner, of manuscript submission, editorial decisions, reviews, and revisions. Please note that if your submission (or its revision) is accepted for publication, each author must submit a signed Exclusive License Form(http://www.srcd.org/Documents/Publications/CD/cdcopyright.pdf) before the manuscript can enter production. Planning ahead to meet this requirement is especially important for manuscripts with multiple authors.

The manuscript file should be formatted with double-spaced, 12-point type, and should include a single paragraph abstract of 100–120 words. Please follow all guidelines on format, style, and ethics provided in the Publication Manual (5th ed.) of the American Psychological Association. Figures included with initial submissions will not be returned. Therefore, please submit only electronic files or copies of figures. Authors should keep a copy of all correspondence, files, and figures to guard against loss.

Manuscript Review

If you have any questions about your submission, please inquire at cdev@srcd.org or call (734) 926-0615. Each manuscript is handled by the Editor or an Associate Editor who consults with one or more Consulting Editors and/or ad hoc reviewers who have relevant expertise. To ensure blind review, cover sheets are removed before review; authors should avoid including any other information about identity or affiliation in submissions. Copies of the submission and associated correspondence are retained in the SRCD archives. For accepted manuscripts, authors are required to prepare a 300–500 layperson's summary for public dissemination purposes. Details are provided to authors as part of final processing.

There is no charge for publication in *Child Development* unless tabular or graphic materials exceed 10% of the total number of pages. Charges are also levied for changes in proofs other than correction of printer's errors. Any inquiries relating to charges or business matters (including reprint orders) should be addressed to Wiley-Blackwell, *Child Development*, Production Coordinator, 350 Main Street, Malden, MA 02148, (781) 388-8200.

Inquiries and suggestions regarding editorial policy may be addressed to: Dr. Jeffrey J. Lockman, Incoming Editor, Department of Psychology, Tulane University, 2007 Percival Stern Hall, New Orleans, LA 70118-5698, lockman@tulane.edu. *Please do not send electronic or paper manuscripts to the above address.* Doing so will delay the processing of your manuscript.

Note to NIH Grantees

Pursuant to NIH mandate, Society through Wiley-Blackwell will post the accepted version of Contributions authored by NIH grantholders to PubMed Central upon acceptance. This accepted version will be made publicly available 12 months after publication. For further information, see www.wiley.com/go/nihmandate.
